(Jenkins, W. M. and Masterton, R. B., 1982; Heffner, H. E. and Heffner, R. S., 1990; Beitel, R. E. and Kaas, J. H., 1993). Following unilateral lesions, localization deficits are restricted to the contralesional hemifield, indicating that each cerebral hemisphere is able to represent independently the contralateral spatial hemifield, as well as the 15–30° of the ipsilateral hemifield closest to the interaural midline (Heffner, H. E., 1997). The effects of acute and chronic inactivations of the auditory cortex are generally similar to the effects of lesions – unilateral inactivations produce contralateral deficits and bilateral inactivations bilateral deficits – but, particularly during longer-term inactivations, may be less severe and may resolve with time (Malhotra, S. *et al.*, 2004; Smith, A. L. *et al.*, 2004). Whether more extensive, chronic inactivations would result in more profound and permanent deficits remains to be seen. It is not surprising that lesions and inactivations produce deficits of differing severity, however, since cortical lesions also result in degeneration within the auditory thalamus and unlesioned cortical areas, thereby increasing the effective size of the manipulation.

3.46.5 Spatial Hearing and the Human Auditory Cortex

Invasive techniques for study of cortical function are only rarely applicable to humans, so the study of spatial hearing mechanisms in the human auditory cortex has emphasized different experimental techniques than are favored in animals. Classical studies in humans relied on sensory testing following cortical lesions due to stroke or trauma. With the advent of structural imaging techniques, lesion studies have been enhanced by the ability to better delineate the extents of lesions. Functional imaging studies employing positron emission tomography (PET), functional magnetic resonance imagery (fMRI), electroencephalography (EEG), and magnetoencephalography (MEG) have only recently been applied to studies of spatial hearing in humans. We will begin by considering the functional imaging results, then will compare those results with results from lesion studies. We will focus on unimodal auditory areas of the temporal lobe; the large literature covering spatial neglect and integration of auditory signals into multimodal areas of the parietal and prefrontal cortex is beyond the scope of this chapter.

The prevailing framework for much recent functional imaging work is the hypothesis that the auditory system possesses segregated what and where pathways analogous to those described in the visual system (Rauschecker, J. P. and Tian, B., 2000; Clarke, S. *et al.*, 2005). Under this model, spatially sensitive and stimulus-feature-sensitive cortical fields are thought to lie posterior and anterior, respectively, to primary auditory regions. Despite methodological differences among studies, a common finding in functional imaging studies is that posterior areas, particularly the planum temporale, are indeed preferentially stimulated by spatially varying or moving stimuli.

Preferential activation in the planum temporale has been found using fMRI and headphone presentation of ear-canal recordings of moving, free-field, amplitude-modulated noise stimuli (Pavani, F. *et al.*, 2002). In a PET imaging study, Zatorre R. J. *et al.* (2002) presented stimuli from an array of small loudspeakers surrounding the listener's head. Regardless of stimulus condition, stimuli produced activation within the superior temporal gyrus, the transverse temporal gyrus (Heschl's gyrus), and posteriorly in the planum temporale. When the source was identical on each trial, they found no cortical areas exhibiting increased activity to more spatially diverse stimulus locations, but when the stimulus varied both spatially and spectrotemporally from trial to trial, foci of activity correlated with spatial diversity were found bilaterally in posterior planum temporale. Similar findings are reported by Warren J. D. *et al.* (2002) using PET and fMRI and are interpreted by the authors as evidence that the planum temporale is involved in the separation of space-related and object-related features of stimuli. Smith A. L. *et al.* (2004) also found activation of that region, but their stimuli were unmodulated wideband noise bursts, which lacked the spectrotemporal variation found necessary by Zatorre R. J. *et al.* (2002).

Using MEG, Fujiki N. *et al.* (2002) recorded auditory mismatch fields for spatial oddball stimuli differing in azimuth or elevation from a standard and found by source analysis that stronger responses to the deviant stimuli were located posterior to those of the standards. Tata M. S. and Ward L. M. (2005), using EEG and electrical source analysis, found that spatial attention can modulate activity near the temporoparietal junction, also posterior to primary auditory areas. All of these results are at least consistent with the existence of a posterior where pathway, although some implicate the planum temporale in both spatial and nonspatial aspects of auditory processing. Hart H. C. *et al.* (2004), using fMRI, observed more

activity in the medial planum temporale for moving stimuli and more activity in the lateral planum temporale for frequency-modulated stimuli, which is suggestive of segregated what and where processing in adjacent posterior areas. In humans and other mammals possessing pinnae, information about sound-source location in the vertical plane is carried by the spectral cues generated by the direction-dependent filtering of the outer ear, but the majority of functional imaging studies have used stimuli varying only in azimuth or in the binaural interaural time- and amplitude-difference cues. Two exceptions to this are the studies by Pavani F. *et al.* (2002; fMRI) and Fujiki N. *et al.* (2002; MEG), both of which employed virtual auditory space stimuli changing location in either azimuth or elevation. The results of both studies suggest activation of similar posterior areas by location changes in either azimuth or elevation. Fujiki N. *et al.* (2002) additionally suggest, however, that monaural spectral cues affect activity more in the right hemisphere than in the left, both in terms of the level and location of activity.

Results from animal studies using electrophysiological (discussed in Sections 3.46.2 and 3.46.3) and lesion (see Section 3.46.4) techniques lead to the conclusion that the representation of each half of auditory space lies primarily in the contralateral cortical hemisphere. A contralateral representation is seen less consistently in human lesion studies (reviewed by Zattore, R. J. and Penhune, V. B., 2001). Substantial individual differences in laterality are seen, due in part to differing etiologies of cortical damage, to the difficulty exactly specifying the lesioned areas, and to possible functional reorganization following cortical damage. Nevertheless, recent well-controlled studies suggest right-hemisphere dominance for auditory spatial representation in humans. Using patients with well-characterized lesions of superior temporal cortex, Zattore R. J. and Penhune V. B. (2001) found that right temporal lobe damage was associated with localization deficits throughout auditory space, whereas similar damage on the left generally resulted in little or no reduction in localization performance. Also, that study showed disturbances in localization in patients with right temporal lobe lesions well anterior to any primary auditory areas. That finding is of course at odds with the consistent identification in imaging studies of posterior, but not anterior, areas as part of the putative where pathway.

3.46.6 Summary and Future Directions

All available data point to the necessity of intact auditory cortex for normal sound localization. The results from studies in experimental animals support the view of a contralateral cortical representation of auditory space in which most individual cortical neurons respond to sounds throughout half or more of auditory space and in which the representation of individual points in auditory space is distributed across widespread neural populations. There is no evidence that any particular cortical areas represent sound-source locations in a way that is dramatically different than in other areas, although some cortical areas seem to show quantitatively stronger spatial sensitivity or enhanced transmission of location-related information (i.e., PAF and DZ in the cat; possibly the caudal belt areas in the monkey). Sound localization by cortical neurons with accuracy comparable to behavioral performance clearly requires the coordinated activity of populations of neurons, likely involving the differential activation of neural populations within each cortical hemisphere tuned to left and right halves of auditory space.

In humans, it is clear that information about sound-source information must reach multimodal areas for spatial processing in the parietal lobe, so in that sense it is clear that there is a posterior–dorsal where stream. Whether that implies a hierarchical organization for spatial processing within the temporal lobe auditory areas remains unresolved, particularly in light of data showing localization deficits resulting from lesions in anterior auditory areas. In contrast to experimental animals, humans seem to show pronounced right-hemisphere dominance for sound localization.

The majority of physiological studies of spatial hearing have been conducted in anesthetized conditions. The few studies in awake animals show greater diversity of spatial sensitivity and greater diversity of neural response patterns than is observed in anesthetized conditions. Future studies must further explore spatial representation in awake conditions, extending studies beyond area A1 into the cortical belt areas. Also, the influence of the behavioral/attentional state of the animal is a key variable that has been largely unexplored. Most studies have used sounds presented in anechoic (or virtual anechoic) conditions. There is a need for more work on mechanisms of

sound localization in realistic environments in which most direct sounds are accompanied by later-arriving reflected sounds.

The most detailed studies of sound localization in the auditory cortex at the single-neuron level have been conducted in nonprimates, particularly in cats. Recent advances in functional imaging have begun to yield new understanding of auditory spatial representation at a more macroscopic level in the human brain. Research is needed on possible homologies between cortical areas in carnivore and primate brains so that insights from the studies in carnivores can be applied more readily toward understanding of mechanisms of spatial perception in humans.

Finally, most work on spatial hearing has focused on identification of the locations of sounds. That is an appropriate starting point because sound-source locations are readily quantified and because many experimental animals show accurate sound-localization behavior. Aspects of spatial hearing that arguably are more relevant to humans, however, are the ability to group together sounds that originate from a particular source and the ability to segregate sounds that originate from different sources. We are optimistic that future physiological studies, informed by psychophysical research, will demonstrate cortical mechanisms for grouping and segregation of sounds in complex acoustic environments.

Glossary

autocorrelation (1) $x(t)x(t+\tau)\mathrm{d}t$, where $x(t)$ is a function of time, t is time, τ is a temporal lag, (2) The Fourier transform of the power spectrum, and (3) An all-order interval histogram.

dominant region for pitch The spectral region that contributes the most to determining the pitch of complex sounds, usually found to be between the second and fourth harmonics of a tonal harmonic complex.

inharmonic tonal complex a tonal harmonic complex in which one or more of the harmonics are shifted up or down in frequency by a constant frequency difference less than or equal to the frequency of the fundamental.

interval order The order of intervals between transients in a click train or neural spikes in a spike train. An *n*th-order interval is the interval between a transient or neural spike and the *n*th transient or spike that follows, for example, a second-order interval is that between every other transient or spike.

iterated rippled noise (IRN) A complex sound usually generated by repeating (through a number of iterations) a process of delaying a noise and adding the delayed noise back to the undelayed noise. The gain of the delayed noise can be adjusted relative to the undelayed noise at each stage of iteration. The pitch of IRN sounds is arguably due to its temporal fine structure and is equal to the reciprocal of the delay and the strength of IRN pitch is a function of the gain and number of stages of iteration.

matched pitch The perceptual pitch of a target sound determined by listeners adjusting the frequency or repetition rate of a comparison sound with a known pitch to match the subjective pitch of the target sound.

missing fundamental pitch The pitch of a tonal harmonic complex in which the spectral component at the fundamental frequency in the spectrum is missing.

musical pitch The perceived pitch of sound that allows a listener to determine musical melodies.

pitch of the residue The low pitch of a tonal harmonic complex that is attributed to the period of the sound's envelope that exists within the neural channels/fibers that are not able to resolve the sound's spectral structure.

pitch-shift of the residue The pitch matched to an inharmonic tonal complex. resolved spectral components Those physical spectral structures of sound that are coded in the spectral-temporal pattern of neural firings within the auditory periphery.

tonal harmonic complex A complex waveform consisting of a fundamental tonal frequency component and its higher harmonics. Sometimes the fundamental is missing.

tone chroma The pitch of a sound that remains constant when the frequency differs by an octave, that is, all of the A notes on the piano keyboard have the same pitch (i.e., pitch chroma).

tone height The pitch of sounds that vary with the fundamental frequency of the sound or by a pitch-matching procedure, for example, the A note in the lower octave of the piano keyboard has a lower pitch (i.e., pitch height) than the A note in the upper octave.

3.47.1 Introduction and the History of the Study of Pitch

From the melody of a song to the quality of one's voice to an attribute of everyday sounds, pitch is a major aspect of auditory perception. Pitch allows us to differentiate one musical melody from another, to distinguish a male talker from a female talker, and pitch differences provide a cue as to which potential sound source may have produced a sound. Pitch is a subjective perceptual attribute of sound, but sound itself does not have a pitch. Sound is characterized by vibrating objects that have physical frequency, physical intensity, and temporal properties. Each of these physical properties of sound is represented in the firing patterns of the nerves of the auditory system. The perceived pitch of sound is the nervous system's way of informing us about the physical properties of the sound sources in our world. If the frequency of a vibrating sound source changes we will usually associate that change in physical frequency as a change in subjective pitch, but as we will see in this chapter many other changes in the pattern of vibration that emanates from a vibrating sound source will also lead to a perception that the pitch of the sound has changed. This chapter attempts to highlight the key developments over the past centuries in the study of complex pitch processing. There have been several excellent reviews of pitch processing (de Boer, E., 1976; Plomp, R., 1976; Meddis, R. and Hewitt, M. J. (1991); Cohen, M. A. *et al.*, 1995; and Plack, C. *et al.*, 2005 to mention a few).

Frequency processing and the ability to perceive pitch are arguably the most informative aspects of sound. Without the ability of the nervous system to determine the frequency of sound, speech would be like Morse code, music would only be drum beats, and we would have a very difficult time telling the difference between the sound from one source and that from other sources. Pitch is nature's way of providing crucial information about the sound from the many sources that may exist in our everyday world. Thus, a major goal for understanding hearing is to understand the relationship between various changes in the physical properties of sound and pitch perception.

Pitch perception has fascinated scholars throughout recorded time (see Boring, E. G., 1942, for a history of sensation and perception). Pythagoras (*c.* 530 BC) studied the relationship between the length of strummed strings and the pitch that strings of different lengths produce. Terpander (*c.* 70 BC) and Didymos (*c.* 50 BC) added much more information about pitch and musical intervals. However, Galileo (1564–1642) is credited with first establishing a relationship between physical frequency and pitch. John Shore invented the tuning fork in about 1715 and it became one of the primary instruments for the study of pitch for almost 250 years. While Newton (1643–1727) is clearly identified with vision as a result of his work with prisms, he also studied several aspects of pitch and its relationship to physical frequency. Baron Fourier's (1822) establishment of the Fourier's theorem was developed as a part of a theory of heat, but this analytic method was quickly applied to sound by scientists such as Ohm G. S. (*c.* 1840). Fourier's theory and analysis are still major analytic tools used in the study of sound and hearing. But, perhaps, no person had a greater influence on the modern view of pitch perception than Hermann von Helmholtz. His book *On the Sensations of Tones* (von Helmholtz, H., 1877) was the classic text on pitch and hearing for almost 50 years and is still cited today.

Helmholtz proposed a theory of frequency and pitch processing that became known as a theory of hearing. Several other theories of hearing followed during the first half of the twentieth century in an attempt to account for the auditory system's ability to process sound frequency and generate a pitch perception. Eventually, there appeared to be two opposing theories. The temporal theory of processing frequency, often credited to Wever E. G. (1949) based

on his volley theory which describes how nerve impulses that are limited in firing rate by the refractory period could still code for high frequencies. The spectral or spatial theory of frequency coding was often credited to George von Bekesy (1960), based on his Nobel Prize (awarded in 1961) winning research on the biomechanical properties of the cochlea. Actually, neither von Bekesy G. nor Wever E. G. espoused that the auditory system used only one method (temporal or spectral) to process frequency, but nonetheless they are often portrayed as proposing opposing theories of frequency encoding and pitch processing. Recent studies have greatly increased our knowledge of how the temporal and spectral aspects of auditory processing help code for frequency and account for pitch processing. However, there remain today two theoretical approaches for pitch processing: spectral and temporal. Several authors (see Moore, B. C. J., 1997) have suggested that theories that combine aspects of both theories offer advantages for accounting for pitch processing. These two main theoretical approaches (temporal and spectral) will be explored in greater detail throughout a great deal of this chapter.

3.47.2 Measuring Pitch as a Subjective Attribute of Sound

As mentioned in Section 3.47.1, sound itself does not have a pitch; pitch is a subjective perceptual attribute of sound. Thus, pitch is defined in perceptual terms and measured perceptually. The standard definition of pitch is, "Pitch is that attribute of auditory sensation in terms of which sounds may be ordered on a scale extending from low to high" (American National Standards Institute, ANSI S3.20-R1978, 1978. There are three such scales that have been used to measure pitch: musical scales, the frequency scale using hertz, and the mel scale.

Musical scales will be discussed in greater detail in Section 3.47.3, but the notes of the musical scale (in Western music: A, B, C, D, E, F, G, and in some cases the sharps, #, and flats, b: Ab, Bb, F#, A#, Eb) are often used as one measure of pitch. In addition, the musical scale may be divided into octaves, and each octave into 12 equal logarithmic divisions called semitones. Each semitone has 100 cents (hence an octave has 1200 cents). Semitones and cents are also used as scales to measure pitch.

A common way to measure the pitch of a target sound is to match the pitch of a matching sound with a known pitch to that of the target sound with an unknown pitch. The physical frequency of the matching sound that is judged equal in subjective pitch to that of the target sound is used as the measure of the pitch of the target sound. Thus, if a sinusoidal matching sound is judged to have the same pitch as a target sound when the sinusoidal sound has a physical frequency of 200 Hz, the target sound is said to have a pitch of 200 Hz. Usually the matching sound is either a sinusoidal tonal sound or a periodically repeating series of impulses (clicks) or click train. The rate of the periodic pulses in the click train is expressed in hertz (e.g., 100 periodic pulses per second is 100 Hz). The click rate is adjusted so that the pitch of the click train matches that of the target sound, and the click rate expressed in hertz of the pitch-matched click train is the pitch of the target sound. Thus, the frequency scale, hertz, is a common measure of pitch.

The mel scale for pitch is not often used anymore, but it also involves a pitch-matching procedure. The standard sound in a mel pitch scaling experiment is a sinusoidal tone of 1000 Hz presented at 40 dB SPL. A listener uses a scaling procedure in which a physical variable of the target sound (e.g., its frequency) is varied until the target sound is perceived as subjectively twice, three times, four times, etc. (or conversely one-half, one-third, one-fourth, etc.) the pitch of the standard sound. A scale relating the judged ratio value to the frequency of the target sound forms the mel scale. A target sound judged to have the same pitch as the 1000 Hz, 40 dB SPL sinusoidal standard sound is defined as having a pitch of 1000 mels (i.e., a 1000 Hz, 40 dB SPL tone has a 1000 mel pitch). A sound with a pitch of 2000 mels has a perceived pitch that is twice that of the standard sound and a target sound with a pitch of 500 mels has a perceived pitch that is one-half of that of the standard sound, etc. Thus, the mel scale is a pitch scale.

Before going further it is worth mentioning that there are two other primary subjective measures of sound: loudness and timbre. Loudness as a measure of sound magnitude is not often confused with pitch, but timbre can be (although the physical magnitude of sound can influence perceived pitch). Timbral differences can also interfere with the perceptual measurement of pitch, especially when the pitch matching procedure is used. Timbre is defined by the ANSI standard (ANSI S3.20-R1978, 1978) as, "Timbre is that attribute of auditory sensation in terms of which a subject can judge that two sounds similarly presented and having the same loudness

and pitch are dissimilar." For instance, a violin and a cello each playing the same musical note for the same duration and at the same loudness generate different auditory perceptions. This difference in perceived sound quality is a difference in timbre. A sinusoidal tone has a different timbre than a click train, even if they have the same pitch, loudness, and duration. The timbre of a click train rather than that of a sinusoidal tone is often more similar to that of target stimuli, and, as such listeners are sometimes better able to make pitch matches using click trains, rather than tones, as matching stimuli. In some cases the pitch of a sound is so weak that the quality of the sound might be better described in terms of timbre rather than pitch.

3.47.3 Musical Pitch

Clearly pitch supports musical melody. Thus, any sound that can produce a musical melody has a pitch and the notes of the melody define the pitch of the sounds. However, subjects can match the pitch of sounds that support musical melody to sounds that are not very good at producing musical melodies. Thus, sounds that cannot produce a melody can have a pitch based on the matching procedure. It is also possible that some sounds that have a pitch can be subjectively judged to differ in musical interval (e.g., by a semitone), but these sounds still do not provide a good melody. Thus, there is a type of hierarchy that exists for pitch measurements. Sounds whose pitch can support melodies are accepted as having the strongest form of pitch and the pitch of these sounds is sometimes labeled musical pitch. The next strongest category of sounds that have pitch are those whose pitches can be judged to match musical intervals, but may not support good melody recognition. The weakest form of pitch arises from those sounds that have a pitch based on pitch-matching measures, but these sounds support neither good musical interval nor melody perception.

Musical pitch can mean two different things. In one case, each note on the piano keyboard has a different pitch, in that a sinusoid with a different frequency would be pitch matched to each note. Alternatively, each of the notes in one octave are often said to have same pitch as the corresponding notes in other octaves (e.g., all A notes on the keyboard have the same pitch). The perceptual similarity of pitches across octaves is one of the perceptual bases of musical transposition. Tone or pitch height is the pitch of a sound that is monotonically related to frequency, whereas tone or pitch chroma is the pitch quality shared by sounds separated by an octave. Thus, in measuring musical pitch, it is often important to differentiate between tone height and tone chroma. There are several pitch illusions (the best example is, perhaps, the Shepard Tone Illusion; Shepard, R., 1964) that are based on the perceptual aspects of tone height and tone chroma, demonstrating that these two aspects of pitch can be confused.

An octave is defined as a doubling of frequency such that the octave above 440 Hz (often the note A in the middle octave of the piano keyboard) is 880 Hz. However, different scales are used by different composers to determine the musical intervals within an octave. For instance, a musical piece played with equal temperament tuning provides that each semitone interval is 200 cents (resulting in the note A being 443 Hz). With just intonation tuning, for example, each semitone interval has a slightly different number of cents (as a result the note A is 440 Hz). Different composers and conductors prefer different types of interval tuning and they often change the tuning based on the piece of music that is to be performed. Thus, the exact pitch of the notes within a musical octave depends on what scale is used for tuning. It is also the case that some musicians prefer that the octave be slightly stretched (slightly greater than a factor of two) in order for the same note in different octaves to have the same tone chroma. Such distinctions can influence the reported pitch of sounds when musical scales of pitch are used to measure pitch.

Most listeners judge sounds whose pitches are separated by an octave to be similar indicating a strong pitch relationship to an octave spacing in pitch (Dowling, W. J. and Harwood, D. L., 1986), that is, tone chroma. A few animals also respond in ways that suggest that they too perceive a special pitch relationship for sounds whose frequencies are separated by an octave (see Blackwell, H. R. and Schlosberg, H., 1943). There is some evidence that the timing of neural spikes in the auditory nerve might reflect a different pattern when sounds have an octave (or stretched octave) relationship than when they do not (McKinney, M. F. and Delgutte, B., 1999).

The pitches produced by musical instruments range from approximately 32 Hz (Pressnitzer, D. *et al.*, 2001) up to about 2000 Hz (about a 6–7 octave range). Sounds with physical frequencies up to the

upper limit of frequency sensitivity (~20 000 Hz) can produce a pitch sensation. However, musical pitch is limited to sounds with frequencies less than approximately 2000 Hz. That is, melodies are not easily discerned when they are played at frequencies greater than 2000 Hz.

Some people have the ability to produce or recognize an exact pitch without the use of a referent sound. That is, if asked, they can sing the note A without any acoustic referent, or if an A note is played they can identify the note as A without another sound providing a referent. Such people are said to have absolute pitch (sometimes called perfect pitch, but absolute pitch is the preferred term). Most people, however, do not have such an absolute pitch ability. Many people (especially musicians) can produce or recognize one pitch relative to that of another pitch (e.g., sounds whose pitches differ by a semitone). That is, they can make relative pitch judgments and as such demonstrate relative pitch. The issue of absolute pitch; What is it? Who demonstrates this ability? Is it learned or genetically based? are questions that have been studied for decades (see for instance, Baharloo, S. *et al.*, 1998).

3.47.4 Place and Temporal Processing of Frequency (and Their Relationship to Pitch)

The elaborate biomechanical structures of the cochlea perform a frequency analysis of the vibratory pattern occurring within the inner ear caused by sound waves impinging on the outer and middle ears (see Dallos, P. *et al.*, 1996). The outcome of this cochlear frequency analysis is neurally transduced by the inner hair cells and relayed by the fibers of the auditory nerve to the brainstem. The auditory nerve, all of the ascending pathways of the auditory system, and the auditory cortex are tonotopically organized in that neural firing rate is dependent on the frequency of the sound input and each region of most neural structures responds best to a limit range of frequencies. For instance, within the auditory nerve, neurons in the middle of the bundle of auditory nerves fire best-to-low-frequency sounds, while fibers toward the outside of the nerve bundle fire best-to-high-frequency sounds. Thus, which set of nerves (i.e., which neural place) responds with the greatest firing rate provides a neural code for the frequency content of the incoming sound. The tuning of auditory nerve fibers and neurons in many other auditory centers is narrow in that only a limited range of frequencies cause the nerve fiber to fire above its spontaneous rate. It is as if the cochlea, inner hair cells, and auditory nerve provide a limited form of a Fourier analysis of the frequency content of sound and this spectral analysis is preserved throughout almost all of the auditory system. The frequency selectivity of the place code for neural frequency analysis is very good. The auditory system can code for frequency differences of less than 1% (see Weir, C. C. *et al.*, 1977).

At the same time the timing of the occurrence of neural impulses are synchronized to the temporal pattern of the vibratory sound waveform. Thus, the period of neural firings are tightly linked to the periodicity of the sound input. However, due to properties of neural transmission, nerves can only follow the temporal pattern of the sound input up to approximately 5000 Hz. Thus, the timing of neural impulses can also code for the frequency content of sound, but is limited to frequencies below 5000 Hz.

Sound can be expressed as the product of two temporal waveforms, a carrier waveform $[c(t)]$ and an envelope waveform $[e(t)]$. Thus, a complex sound $[y(t)]$, can be expressed as $y(t) = e(t)^* c(t)$, where $e(t)$ has a period that is much longer than that of $c(t)$ (see Hartmann, W. M., 1998). The auditory system codes for envelope fluctuations, carrier fine-structure fluctuations, and the spectral transform of $y(t)$, that is, the spectrum of the sound. The spectrum, $H(\omega)$, is the Fourier transform of $y(t)$. As will be discussed in more detail later, both the carrier and the envelope waveforms can produce pitch. Thus, while a neuron may not be able to follow a high carrier frequency, it could fire periodically to the envelope of the sound. As such, the perceived pitch may be that associated with the envelope of the sound, rather than the fine temporal structure of the carrier frequency. Conversely for some sounds the fine structure of the sound provides pitch information. And, the different spectral components of sound are also coded by the tonotopic properties of the auditory system and lead to various pitch perceptions.

As stated above $H(\omega)$ and $y(t)$ are transforms of each other, so knowing one function completely defines the other. That is, temporal information about the envelope, $e(t)$, and/or the carrier, $c(t)$, can be transformed into spectral information and vice versa. As such, temporal and spectral information are simple transforms of each other, and from the physical viewpoint one form of processing (temporal or spectral) is not independent of the other form.

Thus, from the stand point of physics one could not decide if a sound were processed temporally or spectrally. As we will discuss later in this chapter this basic fact of physics has made it difficult to support either a temporal or a spectral theory for how either frequency and/or pitch is processed by the auditory system.

While the physics of sound defines temporal and spectral structure of sound as a simple transform, the actual processing of sound by the auditory system places restrictions on the physical transform. For instance, at the level of the auditory periphery there are separations between the temporal and spectral coding of sound. Thus, it is possible to consider both methods of processing sound (temporal and spectral) for frequency coding and/or pitch perception. Figure 1 represents a simulation of the pattern of neural activity that is likely to occur in the bundle of auditory nerves when the auditory system is stimulated with a tonal harmonic complex consisting of a 220 Hz fundamental and its 30 equal-amplitude higher harmonics (i.e., 220, 440, 660, 880, up to 6600 Hz). Such a stimulus is like that produced by a piano key and generates a clear musical pitch of 220 Hz or the note A in the octave below the middle octave of the piano keyboard. The simulation is based on a model of the auditory periphery (Auditory Image Model of Patterson, R. D. *et al.*, 1995) which simulates the biomechanical properties of the cochlea (a gammatone filter bank, see Van Immerseel, L. and Peeters, S., 2003) and the neural properties of the hair cells (a Meddis hair cell; Meddis, R., 1986).

Figure 1 displays the neural pattern of discharges in the auditory nerve over 100 ms and for auditory fibers tuned to different frequencies – low frequencies at the bottom and high frequencies toward the top of the display. Each horizontal trace represents the histogram of neural discharges from a small set of tuned auditory nerve fibers. The spacing of the center frequency of the tuned fibers (channels) is quasilogarithmic representing an estimate of how the nerve fibers are spatially distributed within the auditory nerve bundle. As can be seen fibers tuned to a frequency region near 220, 440, 660, and up to about 1320 Hz are firing in response to the spectral

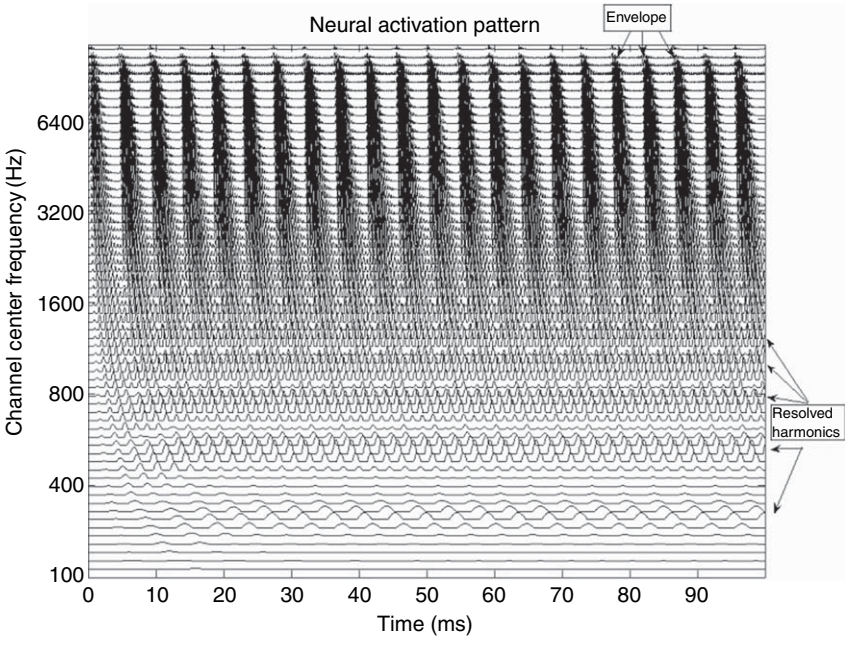

Figure 1 The simulated neural output from the auditory periphery to a tonal harmonic complex with a 220 Hz fundamental and 30 equal-amplitude harmonics. The results are from the computational AIM model (Patterson, R. D. *et al.*, 1995) with each line indicating 100 ms of a histogram of neural responses from auditory channels (fibers) tuned to narrow frequency ranges (the center frequency of the channel/fiber is shown on the *y* axis). Low-frequency channels/fibers are able to resolve the spectral components of the harmonic complex, while the higher-frequency channels/fibers cannot. The higher-frequency channels/fibers preserve the envelope of the harmonic complex and the lower-frequency channels/fibers preserve the temporal fine structure of the individual low-frequency components.

components that make up the harmonic complex. That is, the auditory periphery can resolve the 220 Hz spectral differences in these low-frequency channels. For the higher-frequency fibers (channels), the 220 Hz spacing between harmonic components cannot be resolved by the cochlea and the frequency information from several adjacent harmonics is combined within a single auditory fiber or channel. As a result these high-frequency fibers produce neural discharges that follow the envelope of the waveform. The envelope of the waveform fluctuates periodically at 220 Hz, that is, with a period of 5.5 ms, as do the neural patterns for the higher-frequency channels. In the lower-frequency channels, the neural pattern of discharges follows the temporal fine structure of the low-frequency component (e.g., in the 660 Hz channel, the neural firings occur with about a 1.5 ms period which is the period of 660 Hz), but this ability to follow temporal fine structure disappears as the tuning of the fiber increases toward higher frequencies. Thus, the spectral structure of the harmonic tone is preserved in the low-frequency region, temporal fine structure is also coded in the low-frequency channels, and the envelope of the sound is captured by high-frequency fibers. The major temporal and spectral structures of the harmonic complex are coded in the auditory nerve, but different parts of the auditory nerve code for different aspects of the waveform.

As a result of the coding performed by the auditory periphery it is usually assumed that the frequency of tonal sounds (i.e., a sinusoid) is determined by the place of neural activity for high-frequency sounds, but the tuning of auditory nerve fibers limits frequency resolution. Such a place code can also qualitatively account for the frequency processing of low-frequency tonal sounds, but the resolution of the spectral coding is too poor for low frequencies to quantitatively account for frequency discrimination, so some form of temporal processing is also usually assumed for processing low-frequency tonal sounds. Thus, the pitch of pure tones is assumed to be based on spectral coding for high frequencies and, usually, on a combination of temporal and spectral processing at low frequencies (see Moore, B. C. J., 1993). However, pure tones are not often encountered in one's everyday acoustic world. The key issue for understanding pitch processing is therefore: How are the complex sounds of everyday life processed in order to account for the pitch perceptions associated with such sounds?

3.47.5 Pitch of Complex Sounds (Introduction to and the History of Complex Pitch Perception)

An experiment by Seebeck A. (1841) is often referred to as the beginning of the controversy concerning the relationship between the physical properties of sound (envelope fluctuations, fine-structure fluctuations, and spectral characteristics) and perceived pitch. Seebeck experimented with sirens made of disks with holes in them that rotated over a device that forced air through the holes in the rotating disk. As the disk rotated, air was pulsed at a periodic rate, and the perceived pitch of the disk siren was proportional to the rotation speed (i.e., the periodic rate of air pulses). This led Seebeck to propose that it was the periodic repetition of the air pulses that caused the sensation of pitch (a temporal theory). This was in juxtaposition to Ohm's acoustic law, which said that pitch was associate with the sinusoidal components in the Fourier spectrum of the sound (a spectral theory). Helmholtz supported the spectral approach argued by Ohm and the idea that pitch was associated with the spectral components of sound dominated the pitch literature into the early twentieth century. Since, in some cases, a complex sound made be perceived as having more than one pitch, the issue concerning the processing of the pitch of a something like the disk siren was on the prominent low pitch associated with either the temporal repetition of the waveform (the temporal view) or the fundamental frequency (the lowest sinusoidal component) in the sound's spectrum (the spectral view).

The history of pitch perception and its theories is a series of experiments and theoretical developments based on altering the physical temporal and/or spectral structure of complex sounds and measuring their pitch. Each successive experiment eliminates a physical attribute that the previous experiment argued was the basis for pitch. There was a seesaw of theoretical arguments and developments based on the outcomes of the various alterations of the physical properties of complex sounds. One of the first such alterations was performed by Schouten J. F. (1938) using an optical siren in which the fundamental frequency in the sound's spectrum was missing and yet the low pitch of the siren was that of the missing fundamental. This pitch of the missing fundamental stimulus seemed at odds with the spectral theory of Ohm and Helmholtz and, thus, began the series of experiments and theories that led to our current understanding of pitch perception.

3.47.6 Missing Fundamental Pitch and the Pitch-Shift of the Residue

The optical siren used by Schouten J. F. (1938) would have a long-term spectrum like that shown in Figure 2 (the missing 220 Hz fundamental is shown as a dashed line), and would produce a peripheral neural pattern like that shown in Figure 1, except there would be no neural excitation in the 220 Hz region, since this would be the missing fundamental. Schouten J. F. (1938) found that the low pitch of the sound with and without the missing fundamental was the same. Schouten F. (1938) argued that the pitch of the lower harmonics could be heard out as separate pitches due to the spectral resolving properties of the auditory system (see Figure 1), and that the low pitch of the missing fundamental stimulus was associated with the periodic envelope fluctuations that occur at high frequencies where the harmonics could not be resolved (see Figure 1). Schouten F. (1938) argued that it was the residue pitch associated with the higher unresolved frequencies and their temporal envelope fluctuations that were the basis of the low pitch of many complex sounds.

While the missing fundamental stimulus and its low pitch associated with the frequency of the missing fundamental provided a challenge to a theory of pitch perception based on the spectral presence of the fundamental, it is possible that either the stimulus actually had energy in the spectrum at the fundamental (due to inexact control of the optical siren), or that the nonlinear properties of cochlear transduction reintroduced a spectral component at the fundamental. If a sound with the spectrum shown in Figure 2 is presented to a nonlinear system (cochlear processing is nonlinear), then a nonlinear system could produce spectral components at the difference frequencies between the existing spectral components. Since for the spectrum shown in Figure 2, the difference frequency is the missing fundamental frequency, the nonlinear properties of the cochlea could reintroduce a spectral component at the fundamental. It was well established at that time that nonlinear distortion components such as a difference tone could be detected, especially when stimuli were presented at high levels.

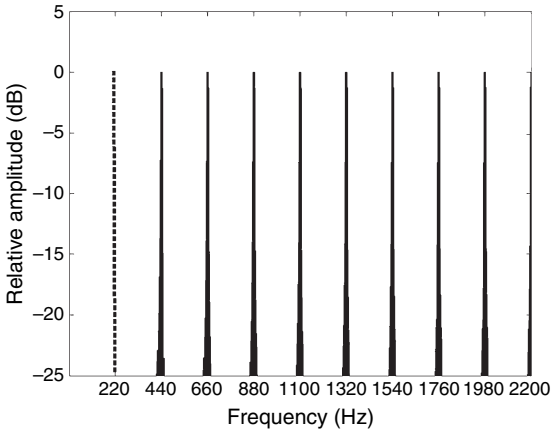

Figure 2 The amplitude spectrum of a missing fundamental tonal harmonic complex. The missing fundamental (shown as the dashed curve) is 220 Hz, and the second through tenth harmonics are present in the complex sound. The low, missing fundamental pitch for this complex sound is 220 Hz, the frequency of the missing fundamental.

Schouten J. F. (1938) showed that no beats could be detected when he added a tone to the missing-fundamental complex with a frequency that was 3 Hz different from the fundamental frequency. If there were any energy in the optical siren sound at the fundamental, one should detect a 3 Hz beat if a tone is added to the siren sound that is 3 Hz different from the fundamental. The fact that no beats were detected helped establish that the siren actually had no (or very little) energy at the fundamental. This experiment also suggests that there was not a strong nonlinear difference tone at the fundamental. Licklider J. C. R. (1955) used a low-frequency noise masker to mask the spectral region of the fundamental in a missing fundamental harmonic tone. He showed that the missing fundamental pitch was still perceived even when any nonlinear distortion products in the spectral region of the fundamental would have been masked. Other studies (e.g., Patterson, R. D., 1969) showed that the pitch of the missing fundamental was only eliminated when the noise masker was presented at a high level that actually masked the harmonics of the missing fundamental harmonic tone. Thus, by the 1960s it was well established that a harmonic tone with no fundamental frequency component produced a strong low pitch at the frequency of the missing fundamental, and this pitch is often referred to as the missing fundamental pitch.

While a spectral theory based on the pitch of complex sounds being determined by the fundamental is defeated by the missing fundamental pitch experiments, a spectral theory based on processing the frequency difference of the resolved harmonics in the missing fundamental stimulus could account for the low pitch, since the difference frequency is the perceived low pitch. That is, even though the

nonlinear distortion produced at the difference frequency is not responsible for the low pitch, some other spectral pitch mechanism could compute the spectral difference (are some form of a spectral difference) and use this as the basis of determining the missing fundamental pitch. We will describe such theories in more detail later in this chapter. Thus, there were still two possible explanations for the missing fundamental pitch: Scouten's temporal theory that it is based on the envelope fluctuations in the high, unresolved frequency region, and the spectral theory based on processing the difference frequency among the resolved harmonics.

De Boer E. (1956; 1961) performed an experiment based on some observations of Schouten J. F. (1940) that challenged both the Schouten residue theory and the spectral difference frequency theory of the missing fundamental pitch. In this experiment, de Boer used an amplitude modulation technique to create a harmonic spectrum shown in the top of Figure 3 (harmonics at 1400, 1600, 1800, 2000, 2200, 2400, and 2600 Hz). The missing fundamental of this harmonic tone is 200 Hz, and this harmonic tone had a strong 200 Hz low pitch. The frequency of each harmonic in this complex was then shifted up in frequency by an amount of Δf, where Δf was less than 200 Hz (e.g., a stimulus might have consisted of 1450, 1650, 1850, 2050, 2250, 2450, and 2650 Hz as indicated in Figure 3). The low pitch associated with such shifted spectra (producing a pitch-shift of the residue) increased noticeably, but the pitch-shifts were small (the pitch-shift of the residue for the stimulus shown in the bottom panel of Figure 3 is about 210 Hz). Since the spacing between the components in the frequency-shifted series is still 200 Hz, the spectral difference theory would predict no change in pitch, that is, the pitch would remain at 200 Hz. It is also the case that the periodicity of the envelope of the unresolved frequency components does not always match the reported pitches for the frequency shifted harmonic series. Thus, these pitch-shift of the residue experiments seemed to cast doubt on both the existing temporal and spectral theories of complex pitch.

Figure 4 shows the pitch-shift of the residue based on the work of Patterson R. D. (1973). Patterson estimated the slope of the best fitting line to the matched pitch of the pitch-shift of the residue for a stimulus with 200 Hz spacing between the 12 consecutive spectral components of a complex tonal sequence when the frequency of the lowest component was varied. Figure 4 indicates the results of these fits. For instance, the far left-hand line indicates that as the lowest spectral component increased from 100 to 300 Hz, the pitch-shift of the residue can range from about 180 to 220 Hz (when the lowest component was 200 Hz, the complex was a 12-tone harmonic complex with a 200 Hz fundamental which yields a 200 Hz matched pitch).

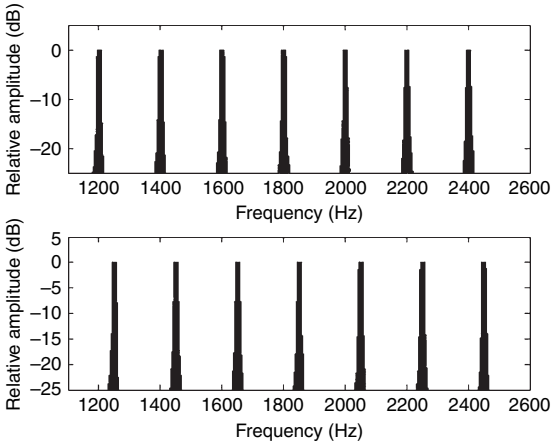

Figure 3 The top panel shows the sixth through twelfth harmonics of a tonal harmonic complex with a 200 Hz fundamental; the low, missing fundamental pitch of this complex is 200 Hz. The bottom panel depicts the case when the components of the harmonic complex shown in the top panel are each shifted up in frequency by 50 Hz. The pitch-shift of the residue for the complex sound of the bottom panel is approximately 210 Hz.

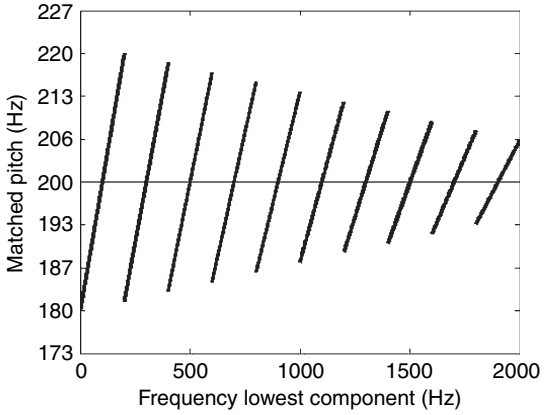

Figure 4 Best fitting straight lines (from Patterson, R. D., 1973) indicating the matched pitched for tonal harmonic complexes, with 12 consecutive tonal components spaced at 200 Hz, plotted as a function of the frequency of the lowest component. The matched pitches indicate the pitch-shift of the residue when the components of a complex sequence are each shifted up or down in frequency.

3.47.7 Dominance Region for Complex Pitch

There are a set of experiments that provide an additional key element in understanding complex pitch processing. While Schouten J. F. argued that the low pitch of the missing fundamental was due to the envelope fluctuations in the high, unresolved frequency regions of the spectrum, spectral theorists used the low-frequency resolved components to estimate a predicted pitch. So the question arises as to which spectral region is more important for the perception of the low pitch of stimuli like the missing fundamental stimulus and the complex stimuli that yield the pitch-shift of the residue. That is, does one spectral region dominate in producing complex pitch perceptions? While there have been several different types of experiments addressing this issue, the one performed by Ritsma R. J. (1962) is usually cited as the first evidence for a dominance region for complex pitch. The most often cited early study of the dominance region for pitch is one by Plomp R. (1967).

In the Plomp R. (1967) study subjects were presented with two stimuli. One stimulus was a complex harmonic tone consisting of the fundamental (ranging between 100 and 2000 Hz) and the 11 higher harmonics. The other stimulus consisted of the same basic fundamental and harmonics, but harmonics below the mth harmonic ($m = 1$–4) were shifted down in frequency by 10% and those above the mth harmonic were shifted up in frequency by 10%. The two stimuli were presented successively in random order and the subject was to indicate if the first or second stimulus was higher in pitch. The results showed that the second and higher harmonics ($m > 1$) dominated the sensation of a rising pitch. The percent of times that the pitch rose when $m = 4$ was far less than for $m < 4$. These results along with those from studies like the earlier one by Ritsma R. J. (1962) strongly suggested that the fundamental was not dominate in determining the low pitch of complex sounds, and the second through about the fourth harmonics were most dominate in determining the low pitch of complex sounds. Thus, the dominance region for complex pitch is assumed to be between the second and fourth harmonics. These results help establish the importance of resolved spectral components in forming the low pitch of complex sounds, as the second through fourth harmonics of a harmonic tone complex would be resolvable by the auditory periphery.

3.47.8 Temporal Fine Structure and Complex Pitch Processing

So far this review of history of the study of pitch processing has centered on the role of the envelope of the unresolved high-frequency components and the spectral differences among low-frequency resolved spectral components. Does the stimulus fine structure have a role in pitch processing? In a series of experiments first done by Small (see Small, A. M., Jr. and Daniloff, R. G., 1967) and then followed up by Bilsen F. A. and colleagues (see Bilsen, F. A. and Ritsam, R. J., 1970) and continued by Yost and his colleagues (see Yost, W. A., 1996a), the answer appears to be yes. A key stimulus that implicates temporal fine structure in pitch processing is rippled noise or more recently iterated rippled noise (IRN, see Yost, W. A. *et al.*, 1996).

IRN stimuli are usually generated by delaying a noise waveform by an amount, d (in ms), and adding the delayed noise (perhaps after changing the gain, g, of the delayed noise relative to the undelayed noise) back to the undelayed noise. This process can be repeated (iterated) many times resulting in an IRN stimulus. Figure 5 displays the network used to generate IRN stimuli and Figure 6 shows the time-domain waveform (top panel) and the amplitude spectrum (bottom panel) for an IRN stimulus generated with a delay of 4 ms, two iterations (as depicted in Figure 5), and when the relative gain (g) was 1 (i.e., the delayed and undelayed noises were equal in level). As can be seen in Figure 6 (top panel), the apparent envelope of the IRN stimulus appears noisy but unmodulated and there are spectral peaks at $1/d$ (250 Hz) and its higher harmonics (bottom panel). The spectrum is like a noisy version of that of a harmonic tone complex with a fundamental of 250 Hz. This IRN stimulus has a 250 Hz pitch (i.e., a pitch equal to $1/d$ which also indicates the lowest-frequency spectral peak). If the lower-frequency spectral peaks are filtered out of this IRN stimulus so that only unresolved higher frequency spectral peaks remain, the pitch of the IRN stimulus remains

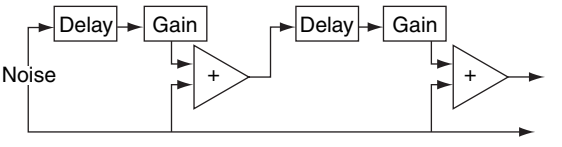

Figure 5 The delay, gain, and add circuit used to generate iterated rippled noise (IRN). Two iterations are shown.

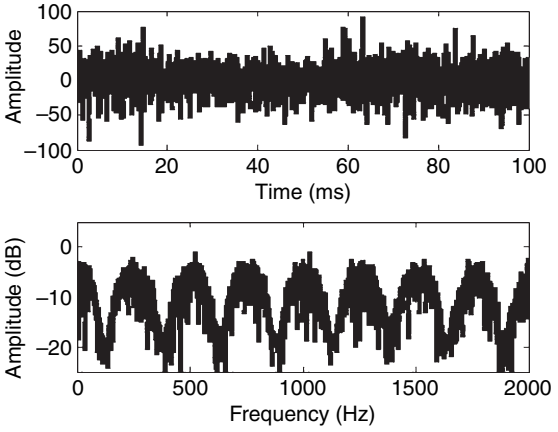

Figure 6 The time-domain waveform in the top panel for an iterated ripple noise (IRN) sound generated with a 5 ms delay, gain of one, and two iterations (see Figure 5). The bottom panel indicates the amplitude spectrum of the IRN sound, showing the noisy spectral structure with spectral peaks at 200 Hz and its higher harmonics. The pitch of this IRN sound is 200 Hz (the reciprocal of the 5 ms delay).

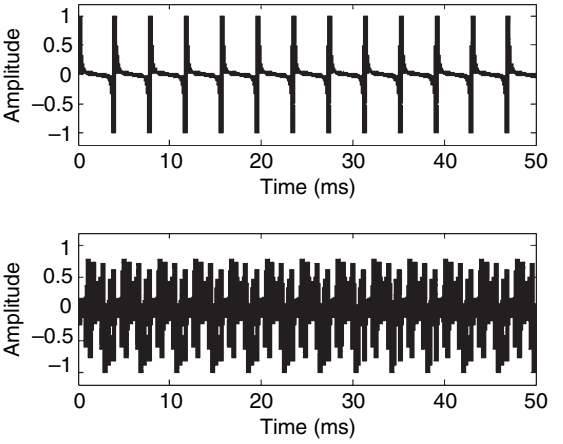

Figure 7 The time-domain plots of a tonal harmonic complex with a 250 Hz fundamental and 50 harmonics. In the top panel, the tonal components all have the same starting phase and in the bottom panel the starting phases of the components are random. Each tonal complex has a 250 Hz pitch, with the saliency of the pitch when the components are in-phase being stronger than when the tonal components are in random phase.

strong at 250 Hz (although not as strong as when the lower-frequency, resolved peaks are present; Yost, W. A., 1982). Thus, the 250 Hz pitch of the IRN stimulus does not appear to depend on resolved spectral components or on a well-defined temporal envelope. As we will discuss in more detail later on, the pitch of IRN stimuli can be explained based on temporal fine-structure processing.

The results from IRN experiments are consistent with those from other experiments in which the time-domain waveform of the complex sound is more random than that produced by a simple harmonic tone complex. Figure 7 displays the time-domain waveforms of a harmonic tonal complex in which the starting phases of each component are the same (top panel) or are randomly chosen (middle panel). Most experiments on complex pitch perception use harmonic tonal complexes with all of the starting phases of the tonal components fixed as indicated in the top panel of Figure 7. Licklider J. C. R. (1955) indicated that a random-phase harmonic tonal complex did not appear to have a missing fundamental pitch. However, several different studies (see Patterson, R. D., 1973) showed that the pitch of a tonal complex remained at the frequency of the fundamental regardless of the starting phase distribution of the harmonics (except in certain conditions, Carlyon, R. P. and Shackleton, T. M., 1994). Several studies of the pitch of harmonic tonal complexes with random starting phases indicated that while the pitch did not appear to be affected by the starting phases, the pitch sensation for a random starting phase harmonic tonal complex appeared to be less salient than that for harmonic tonal complexes generated with all components having the same starting phase (see Plomp, R., 1976). While varying the starting phases of the components in a harmonic tonal complex changes the temporal envelope of the sound, such changes do not change the amplitude spectrum and certain aspects of the temporal fine structure. There have been many studies that have investigated the complex pitch of tonal complexes generated with a variety of starting phase configurations, and it is clear in several cases that the temporal waveform that results from a particular starting phase configuration can influence the perceived pitch of tonal harmonic complexes (see Carlyon, R. P. and Shackleton, T. M., 1994).

So, perhaps complex pitch is determined by temporal fine structure. An experiment by Burns E. M. and Viemeister N. F. (1981) indicates that this is not always the case. Burns E. M. and Viemeister N. F. (1981) showed that a sinusoidally amplitude modulated wide-band noise (SAM noise) produced a very weak pitch that supports a weak form of melody recognition. Since the noise waveform has a random temporal fine structure and a random long-term spectral profile, the only possible cue for the pitch of SAM noise is its amplitude modulated envelope.

Thus, it appears as if neither spectral resolvability, nor envelope, nor temporal fine structure by themselves is necessary and sufficient to produce the pitch of complex stimuli. There is also the problem that the pitch-shift of the residue experiments appears to eliminate a spectral difference of resolved harmonics theory and the envelope of unresolved harmonics theory of complex pitch perception. In order to understand how some of these issues get partially resolved it is necessary to explain some of the models used to account for the data involving the pitch of complex sounds.

3.47.9 Models and Theories of Complex Pitch Processing

As explain above models and theories of pitch processing are either spectral, temporal, or combined spectral–temporal models. Most spectral models are based on assuming that the pitch of complex sounds is based on the best-fitting harmonic structure that can be applied to the resolved spectral components of a complex sound. The fundamental frequency of the best-fitting harmonic series to the spectrum of the complex sound is the predicted pitch of the complex sound. In the case of the missing fundamental stimulus consisting of a harmonic tonal complex without the fundamental present, the best-fitting harmonic series would be the same harmonic series as that of the entire complex, and its fundamental (i.e., the missing fundamental in the actual stimulus) would be the predicted pitch, and this, of course, is a correct prediction. In most models the fit is not done based on all of the harmonics of a complex sound, it is only done for the harmonics within the dominance region for complex pitch, that is, the fit is only made to the second to fourth harmonics of a complex sound (or the fit is weighted in favor of the dominance region for pitch). Not only does this allow the models to be consistent with the fact that there is a dominance region for complex pitch, it allows these spectral models to account for the pitch-shift of the residue effect that appeared to be in conflict with a spectral account of complex pitch.

Figure 8 is a schematic depiction of how spectral models might account for the pitch-shift of the residue. In the case shown in Figure 8 the spectral components of a 200 Hz fundamental harmonic tonal complex with six components are shifted upward 50 Hz, so that the components are at 250, 450, 650, 850, 1050, and 1250 Hz (see Figure 3). This

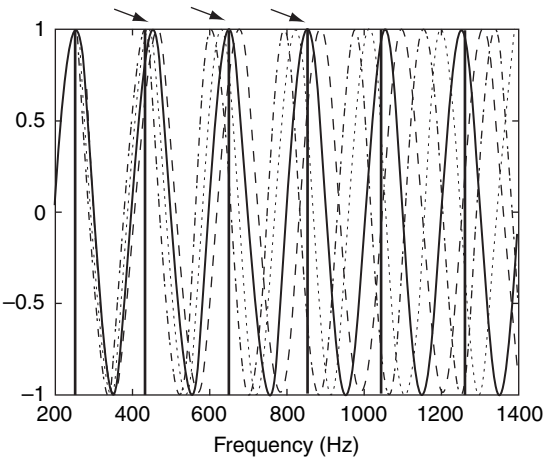

Figure 8 A schematic depiction of how spectral models estimate the pitch of a complex harmonic sound that have shifted spectral components. The spectrum of the sound is represented by the vertical lines at 250, 450, 650, 850, 1050, and 1250 Hz (see Figure 3). The four sinusoidal functions depict attempts at finding the best harmonic fit to this tonal complex that produces a pitch-shift of the residue. The solid sinusoidal function provides the best fit to the second to fourth harmonic components (marked with the arrows). The second to fourth harmonics are those in the dominant region for pitch. The frequency of this best fitting solid curve is 210 Hz, which is the pitch of the pitch-shift of the residue for this complex sound.

complex sound representing a pitch-shift of the residue condition would have a low pitch of about 210 Hz (see Patterson, R. D., 1973). That is, while the spectral spacing of the resolved low-frequency components is 200 Hz the perceived pitch is not 200 Hz, it is about 210 Hz. The spectral components of the six-component complex sound are shown as the vertical lines. The sinusoidal functions are simulations of finding a harmonic function to fit the spectral location of the six spectral components of the complex sound. The idea of most spectral models is to find a harmonic function (e.g., a sinusoid) whose second to fourth peaks best match the spectral location of the second to fourth spectral components of the complex sound (these three components are indicated with arrows in Figure 8). None of the sinusoidal functions makes a perfect fit to the second to fourth spectral components of the complex sound, but the solid sinusoidal curve comes closest to a match. The frequency of this sinusoidal fit is 210 Hz, and as such it would represent the predicted pitch for this stimulus, and 210 Hz is the pitch that most listeners would assign to this sound.

Such spectral models require several assumptions: (1) They need a process for deciding on what

constitutes a best fit. (2) They require some process that establishes the second to fourth spectral components as dominant. (3) The models must assume some sort of ability of the peripheral auditory system to resolve the spectral structure of a complex sound. (4) And, of course, they need to account for the many data that exist concerning the pitch of complex sounds. Four such formal models or theories have been proposed that are spectral approaches along the lines explained above: Wightman's (Wightman, F. L., 1973) pattern transformation model, Goldstein's (Goldstein, J. L., 1973) optimum-processor model, Terhardt's (Terhardt, E., 1974) learning-matrix model, and the Cohen M. A. *et al.* (1995) spectral-network model. Each model is able to make quantitative predictions for the pitch of most complex sounds. The spectral-network model (Cohen, M. A. *et al.*, 1995), being the most recent, is able to account for the largest amount of pitch data, but many of its assumptions and processes are derived directly from the earlier models of Wightman, F. L. *et al.*, and some of the work of Yost W. A. (1982). The learning-matrix model of Terhardt E. (1974) is a comprehensive model that also deals with several other auditory effects like consonance and dissonance. Wightman's (Wightman F. L., 1973) pattern-transformation model is actually based on the Fourier transform of the spectrally resolved amplitude spectrum of the complex sound. The Fourier transform of the amplitude spectrum is the autocorrelation function, and the pattern-transformation model uses the autocorrelation function as a means to derive spectral predictions for the pitch of complex sounds.

Most formal temporal models of complex pitch are based on Licklider's (Licklider J. C. R., 1951) original idea that autocorrelation could be used to account for pitch perception and processing. In this case the autocorrelation approach is conceived in the time-domain and the temporal features of the autocorrelation function are used to account for the pitch of complex sounds. Peaks in the autocorrelation function at particular lag times indicate high correlations of temporal regularity in the complex sound. These temporal models assume that it is this temporal regularity (either in the envelope, fine structure, or both) that accounts for the pitch of complex sounds.

Figure 9 indicates how in general autocorrelation is used to account for the pitch of complex sounds. The stimulus for this description is a 19-tone harmonic complex with a 200 Hz missing fundamental (i.e., the fundamental at 200 Hz is missing and the second through twentieth harmonics are present) and the starting phase of each of the 20 components is random. This complex sound produces a 200 Hz low pitch. The time-domain waveform is shown in the top of Figure 9. The bottom panel of Figure 9 shows the normalized autocorrelation function of this sound. As can be seen there is a large peak at a lag of 5 ms and progressively smaller peaks at lags of integer multiples of 5 ms. Some function of the reciprocal of the lag of the location of largest peak in autocorrelation function (200 Hz in this case) is used to predict the pitch of the complex sound, and the relative height of this peak has been used to account for measures of the saliency of the perceived pitch (pitch saliency or pitch strength will be discussed later in the chapter). In addition to using the peaks in the autocorrelation function, these temporal models also have processes that allow them to predict the pitch-shift of the residue effect, since additional processing of the sound is required in order for the peaks in the autocorrelation function to appear at the appropriate lags that would allow the models to account for the pitch-shift of the residue.

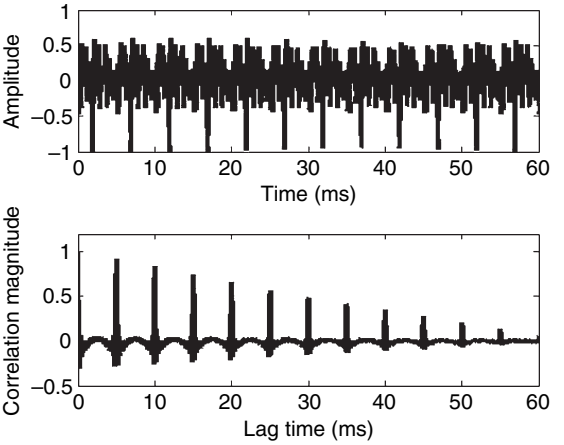

Figure 9 The top panel shows the time-domain waveform for a 19 component, 200 Hz missing fundamental complex (i.e., the spectral components are at 400–4000 Hz, every 200 Hz) generated with random starting phases for each component. This complex stimulus has a 200 Hz pitch. The bottom panel shows the normalized autocorrelation function with a major (largest) peak at 5 ms. Temporal models based on autocorrelation use the reciprocal of the delay for the major peak (200 Hz = 1/5 ms) to predict the pitch of the complex sound and the relative height of this peak to account for pitch saliency/strength.

Meddis R. and Hewitt M. J. (1991) and more recently Meddis R. and O'Mard L. (1997) developed the most complete model based on autocorrelation to account for the pitch of most of the sounds that have

been studied in the complex pitch literature. Yost and Patterson and their colleagues (see Yost, W. A. *et al.*, 1996; Patterson, R. D. *et al.*, 2000) have applied variations of this theme to deal with iterated rippled noise stimuli. De Cheveingé A. (1998) developed a variation of autocorrelation that works well in predicting some of the complex pitch data, but it has not been applied to as large a data set as the Meddis R. and Hewitt M. J. (1991) model. Cariani P. A. and Delgutte B. (1996a; 1996b), used an autocorrelation approach to analyze auditory-nerve data that accounts for a large number of perceptual pitch findings, and this approach will be discussed later in this chapter. Recently, Bernstein J. G. and Oxenham A. J. (2005) modified the model of Meddis R. and O'Mard L. (1997).

All of these autocorrelation-like approaches usually assume that the complex sound is first processed by the auditory periphery and the sound is represented in neural channels each tuned to a particular frequency region. Figures 10 and 11 indicate such an approach which is similar to that used by Meddis R. and Hewitt M. J. (1991), Yost W. A. and colleagues (1996), and Patterson R. D. *et al.* (2000). The stimulus used for Figures 10 and 11 was an IRN stimulus generated such that the spectral peaks started at 100 Hz and were spaced every 200 Hz above that (i.e., 100, 300, 500, 700, 900 Hz, etc.). This stimulus is an IRN equivalent of a pitch-shift of the residue type stimulus in that the fundamental is 100 Hz with every other (even) harmonic of 100 Hz missing (i.e., this is equivalent to shifting the spectral peaks of a 200 Hz fundamental tonal complex down by 100 Hz). In general, subjects either match the pitch (Yost, W. A., 1996a) to that of the fundamental (100 Hz in the example) and/or at about plus or minus

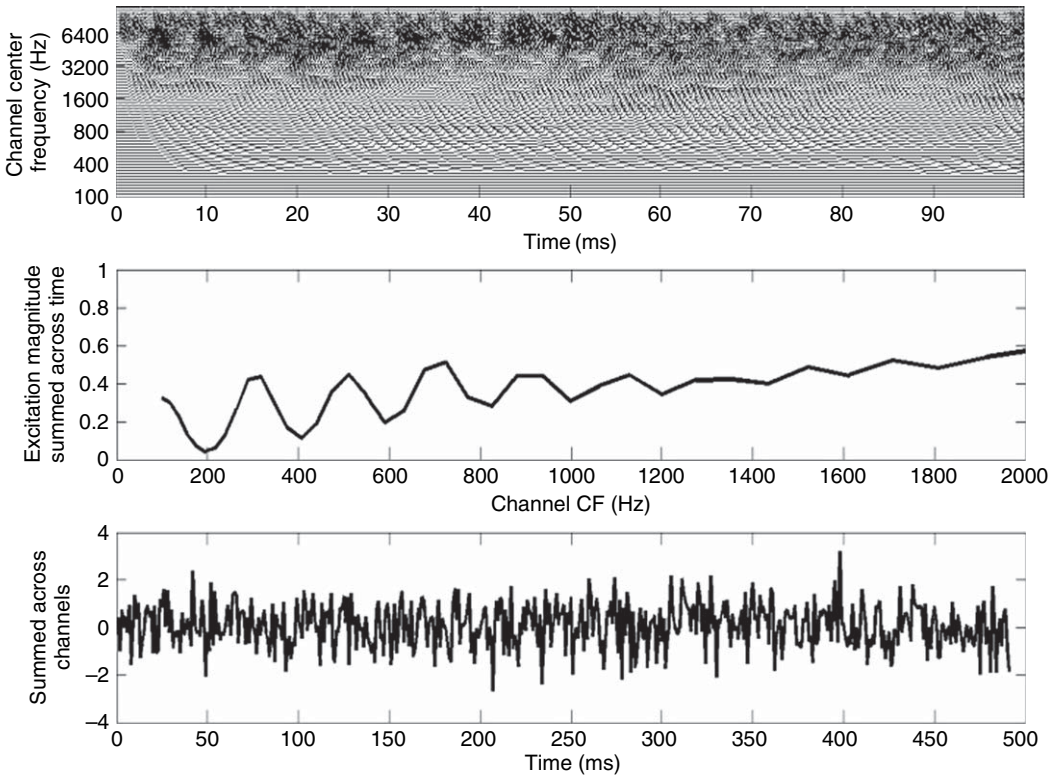

Figure 10 Three displays for an iterated ripple noise stimulus (IRN) generated such that the spectral peaks are at 100, 300, 500 Hz, etc. This IRN sound generates pitch-shift of the residue pitches, with matched pitches being at either 100 Hz, about 180 Hz, and about 220 Hz. The top panel shows the neural activation pattern using the AIM model (see Figure 1). It is difficult to see either a spectral (in the vertical direction) or a temporal structure (in the horizontal direction) to the simulated neural display for this IRN sound. The middle panel shows the auditory spectrum (excitation pattern) computed by summing over time for each frequency channel of the top display. The spectral shape of the IRN sound with resolved peaks at 100, 300, 500, 700, 900, and perhaps 1100 Hz can be seen. The bottom panel represents one view of the temporal information contained in the top display by summing across all frequency channels. None of these three displays contains information that would predict the three pitches typically matched to this IRN stimulus.

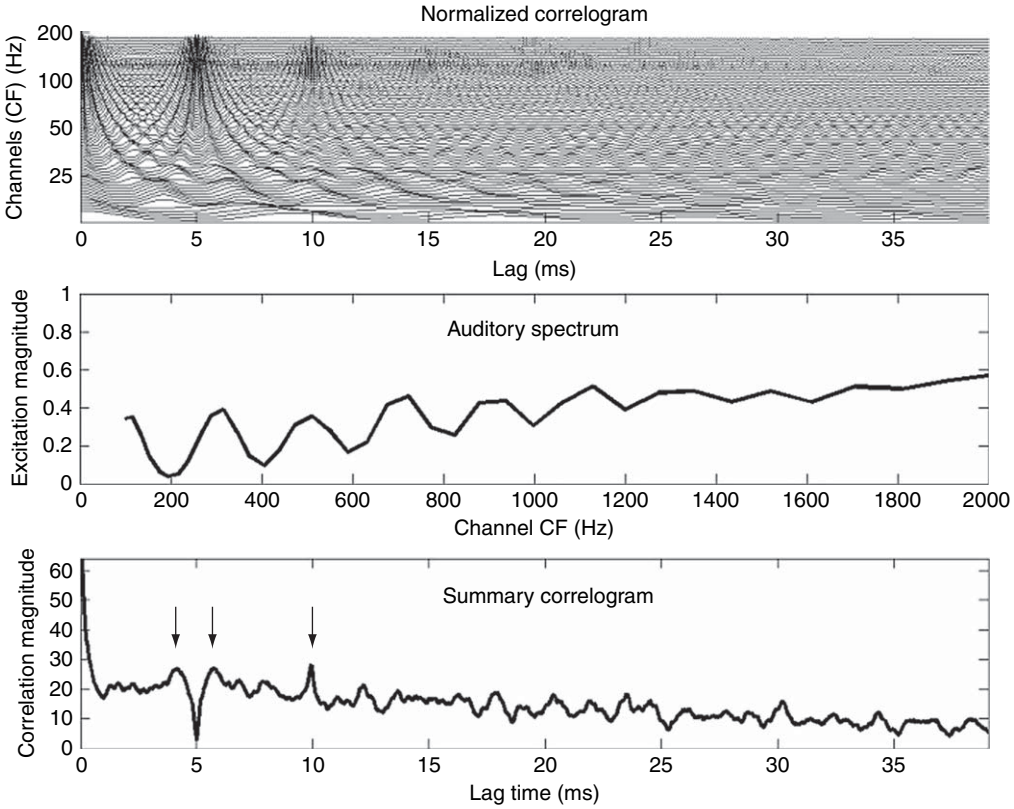

Figure 11 An autocorrelation function is applied to each channel of the display in the top panel of Figure 10 and the output of this computation is shown in the top panel of Figure 11 as a normalized correlogram. The middle panel is the same as that in Figure 10 in that the information in each frequency channel of the top display of Figure 11 is summed over time generating an auditory spectrum. In the bottom panel the autocorrelation information in the correlogram (top display) is summed across all channels generating a summary correlogram. The summary correlogram was constructed based on weighting the correlations in each channel by a function that emphasized the spectral region in the region of 300–700 Hz, which is the approximate dominant pitch region for this stimulus. The arrows point to the three largest peaks in the summary correlogram. The reciprocal of the peak at 10 ms is 100 Hz, and those of the two peaks near 5 ms are 180 and 220 Hz. These are the three matched pitches associated with this IRN stimulus.

10% of the spectral spacing of the peaks (±10% of 200 Hz; and/or 180 and/or 220 Hz in the example).

Figure 10 in the top panel displays the output of the same computational model (AIM, Patterson, R. D. *et al.*, 1995) used for Figure 1. This display is a simulation of the neural information that might flow from the cochlea to the brainstem in the auditory nerve for this IRN stimulus. In the middle panel of Figure 10, the neural activity has been summed across time for each channel and this display is a type of spectral representation (auditory spectrum or excitation pattern) that might be available to the auditory nervous system (the resolved spectral peaks in the lower frequency region can be seen, but not at high frequencies). In the bottom panel of Figure 10, the summed neural activity across channels is displayed indicating the noisy nature of the neural temporal information provided by the auditory periphery. At this level of processing, none of the three displays provides a direct prediction for the pitch(s) of this IRN stimulus.

In the top panel of Figure 11, an autocorrelation of the neural information in each channel is performed. This provides a correlogram showing the correlation of temporal regularity in each tuned channel. The middle panel in Figure 11 indicates the auditory spectrum as the sum across autocorrelation lag as shown in the middle panel of Figure 10. In the bottom panel of Figure 11, the autocorrelation functions of the correlogram shown in the top panel are summed across channels producing a summary correlogram. However, before summing across the channels the information in each spectral channel was weighted by a function that emphasizes the

spectral peaks in the dominance region for pitch (e.g., in the spectral region between 300 and 700 Hz). The weighting is similar to bandpass filtering the IRN stimulus with filter cut-offs at 300 and 700 Hz. Work by Bilsen F. A. and Ritsma R. J. (1967/1968) and Yost W. A. (1982) have shown that such dominance region weighting and filtering of IRN stimuli is important for accounting for the pitch-shift of the residue for these types of IRN stimuli. In the summary correlogram of Figure 11 there are three major peaks (indicated by the arrows). They are at lags of approximately 4.5 ms (its reciprocal is 220 Hz), 5.6 ms (its reciprocal is 180 Hz), and 10 ms (its reciprocal is 100 Hz). As indicated above, these summary correlogram peaks are consistent with the pitches of this IRN stimulus as reported in the literature (see Yost, W. A., 1982).

In addition to autocorrelation models, some researchers (see Langner, G. *et al.*, 1998) have suggested that neural circuits or units that process amplitude modulation (i.e., the envelope of sound) may also participate in pitch processing. That is, many sounds that are amplitude modulated produce a perceived pitch (as discussed previously in this chapter), and since there is evidence that neural units in the higher auditory pathway (e.g., inferior colliculus, Langner, G. and Schreiner, C. E., 1988) and auditory cortex (Schreiner, C. E. and Urbas, J. V., 1986) are selectively sensitive to different modulation rates, these units might be responsible for encoding pitch. The computational modulation filerbank model of Dau T. *et al.* (1997) has recently been applied to account for several data sets involving complex pitch. The issue of amplitude modulation and envelope as they impact complex pitch perception will be discussed later in this chapter.

3.47.10 Which Type of Model Provides the Better Predictions for Complex Pitch?

Both temporal and spectral models provide very good predictions for a great deal of the pitch data in the literature. Given the nature of the transforms between time and frequency, a temporal model can often be rewritten as a spectral model and vice versa. However, when the models are couched in terms of spectral resolvability, then such transformations are not always possible. Spectral models cannot account for the pitch of complex stimuli when the stimuli are generated in such a way that the complex stimulus's spectral structure is not resolvable by the auditory system (e.g., when a tonal harmonic complex with a low-frequency fundamental is high-passed filtered). In addition, spectral models cannot account for the pitch of amplitude modulated noises (Burns, E. M. and Viemiester, N. F., 1981).

Temporal models can often account for pitch data for stimuli with unresolved spectral structure and for modulated noise stimuli. However, the pitch of complex stimuli with unresolved spectral components is weak as is the pitch of amplitude modulated noise. In many cases the pitch of stimuli without resolved components is so weak as to not be able to support musical intervals or melodies and the quality of the sound is sometimes referred to as rattle pitch (Plomp, R., 1976) indicating that the perceptual sensation maybe more timbre like than pitch like. Thus, those stimuli that produce robust pitches are those with resolvable spectral components and these pitches can be well explained by spectral models.

Spectral models can also explain the ability of listeners to determine the pitches of the lower-frequency individual components in a tonal harmonic complex. Support for the spectral theories and their ability to account for some of the properties of the spectral theories comes from experiments with inharmonic tonal complexes. Experiments (see Moore, B. C. J. *et al.*, 1986; Lin, J. Y. and Hartmann, W. M., 1998) using tonal inharmonic complexes are often designed to determine if one tonal component in a harmonic complex is mistuned by shifting it up or down in frequency, would that tone appear perceptually as a separate pitch from that of the low pitch of the complex, and if so would the low pitch of the complex change because that tonal complex was no longer contributing to the low pitch of the complex? If, for example, the third harmonic (600 Hz) of a 200 Hz fundamental tonal harmonic complex is shifted by 8% or more (e.g., from 600 to 650 Hz), then the pitch of this tonal component (i.e., a pitch at 650 Hz) and a pitch near 200 Hz are perceived. That is, this inharmonic tonal complex with all tonal components except one (the 650 Hz mistuned tonal component) being harmonics of 200 Hz produces two pitch perceptions; one near 200 Hz and one at 650 Hz. If the pitch-shift is less than about 8%, only the 200 Hz low pitch is perceived. When the pitch of the mistuned harmonic (i.e., the 650 Hz component) is perceived separately, the low pitch is also shifted slightly from 200 Hz. These results suggest that the harmonic match used in most spectral models needs to be accurate to about 8% of the frequencies of the

harmonics in the stimulus. It is as if the harmonics of a tonal harmonic complex are passed through a spectral sieve before the harmonic structure is determined, with each sieve or channel having a spectral width of about 8%. Thus, many of the data from such inharmonic pitch studies support spectral models of pitch processing (the work of Hartmann, e.g., Lin, J. Y. and Hartmann, W. M., 1998; and Moore, e.g., Moore, B. C. J. *et al.*, 1986 should be consulted since there are several important findings from such experiments that impact the details of how these inharmonic stimuli effect pitch processing).

3.47.11 Pitch Strength or Pitch Saliency

While a wide variety of simple and complex sounds produce pitch, the saliency of the pitch varies considerably from stimuli that produce extremely strong pitches that support melody perception (e.g., an unfiltered periodic click train) to stimuli that produce pitches that are so weak that the perceptions are more like subtle timbre changes (e.g., very-high-passed filtered IRN stimuli or modulated noises). Four different techniques have been used in one way or another to estimate the strength or saliency of perceived pitches, or at least relative pitch strength. In the first technique, a few studies have used magnitude estimation to derive estimates of pitch strength (Fastl, H. and Stoll, G., 1979; Yost, W. A., 1996b; Shofner, W. P. and Seles, G., 2002). Iterated rippled noise stimuli offer the advantage of having two variables that alter the pitch strength of the IRN stimuli (i.e., the number of iterations of the add and delay network or the gain, *g*, applied to the delayed noise before it is added back to the undelayed noise, see Figure 5 and Yost, W. A. *et al.*, 1996). Listeners are asked to discriminate between IRN stimuli and noise stimuli that have no pitch and one of the parameters that varies pitch strength is changed allowing for an estimate of the parameter value that yields a threshold ability to discriminate between the noise and the IRN stimuli. In experiments in the second technique, the discrimination is between two IRN stimuli each producing a different pitch and again the variable that controls pitch strength is varied until the listener is at threshold in making the discrimination between the two IRN stimuli. In these IRN discrimination experiments the discrimination threshold value of the variable that controls pitch strength (e.g., the threshold value of the gain, *g*) is used as a measure of pitch strength. A third technique involves asking subjects to make a musical interval or musical melody judgments. When a variable that presumably controls pitch strength is varied so that an interval or melody cannot be accurately determined, the pitch is said to be too weak to support pitch perception. Pressnitzer D. *et al.* (2001) have used such a technique to measure the lower limit of pitch, which they found to be an interaction between the lowest spectral component in the sound and the duration of the temporal regularity in their complex sounds. The lowest of the lowest pitches appears to be near a temporal-regularity duration of about 30 ms or a pitch of about 33 Hz. The fourth method for estimating pitch strength or saliency is a pitch discrimination task, or since these experiments involve harmonic sequences of one sort or another the task is equivalent to a fundamental frequency (F0) discrimination task (see Carlyon, R. P. and Shackleton, T. M., 1994). Since a speech sound, like a vowel, can be simulated with a tonal harmonic sequence (the fundamental frequency simulates the frequency of vocal cord vibration), F0 discrimination is often measured for synthesized vowels (See Chapter 3.48). A great deal of the work on F0 discrimination involves the study of spectral resolvability and complex pitch which will be discussed next section.

In general, measures of pitch strength have shown that the pitch of stimuli with unresolved spectral structure is considerably weaker than the pitch of stimuli with resolved spectral structures. Some studies have shown that the pitch of complex sounds that have energy in the dominant pitch region is stronger than when the sounds do not contain spectral information in the dominant pitch region. The IRN pitch strength/discrimination experiments have supported the use of the height of the peaks in autocorrelation or summary correlogram functions as a predictor of pitch strength. There is also evidence that a 12-component tonal harmonic complex produces a stronger pitch than a six-component complex and the pitch of a tonal harmonic complex generated with random starting phases is weaker than when the starting phases are fixed (Fastl, H. and Stoll, G., 1979). Some pitch strength studies have been used to point out that in most cases there are at least two percepts associated with many complex sounds that produce a pitch (Patterson, R. D. *et al.*, 2000). There is the low-pitch and there is the timbre of the overall sound. For many stimuli the complex sound is like a mixture of two sound sources, one with a pitch mixed with one with a distinct timbre. In these cases, the

pitch strength estimate indicates the saliency of the pitch source as compared to that of the timbre source.

3.47.12 Spectral Resolvability, Harmonic Number, and Pitch Perception

There is a growing literature that indicates that pitch processing depends in several ways on either the resolved harmonics (or resolved structure) of a complex sound or on the number of lower harmonics. That is, pitch processing might not depend on spectral resolvability *per se*, but rather on the number of lower-frequency harmonics contained in the complex sound (see Bernstein, J. G. and Oxenham, A. J., 2005 for a review). A key paradigm for studying the role of the harmonic structure of complex sounds is the measurement of fundamental frequency (F0) processing for tonal harmonic complexes filtered in different ways to restrict the number of harmonics and/or to control the spectral region where the harmonics exist and/or to alter the degree to which the harmonics might be resolved by the auditory system. In several of these studies the phases of the complexes were varied in different ways to test the idea that if the spectral components of a complex are resolved, the phase of one resolved component might not interact with that of another resolved component since each resolved component is processed by a separate auditory channel or filter. However, for unresolved components that are presumably combined in one spectral channel of filter, the phases of the components would interact (see Carlyon, R. P. and Shackleton, T. M., 1994; Shackleton, T. M. and Carylon, R. P., 1994). The results from several studies indicate that F0 processing and its interaction with the phases of the components is different for resolved than for unresolved components. Some of the data suggested that for certain stimuli in which some of the components are resolved and some unresolved that neither a current spectral nor a current temporal model could account for all of the data, but a spectral model could account for some of the data and a temporal model for the remainder of the data. This suggested that there might be two pitch mechanisms, one spectral and one temporal. Subsequent experiments indicated that there were not two mechanisms and that modifications to the models, at least to the autocorrelation temporal model, could account for many of these newer data (see Bernstein, J. G. and Oxenham, A, J., 2005).

Several experiments (see Bernstein, J. G. and Oxenham, A. J., 2003) suggest that good F0 discrimination and processing that indicates good pitch processing is not determined on spectrally resolved components *per se*, but rather on the number of low-frequency harmonics that are present in the waveform. It appears that the first 10 harmonics are important for good performance in F0 processing somewhat independent on the components spectral resolvability. A summary correlogram uses all of the information from lower-frequency (resolved) and higher-frequency (unresolved) components in producing pitch predictions. Thus, a summary correlogram model should be able to predict pitch and F0 processing as a function of harmonic number. However, the summary correlogram models also include processes that account for the lack of phase locking in the high-frequency channels of the auditory system (i.e., a lack of an ability for high-frequency fibers to follow temporal fine structure). Thus, changes in the summary correlogram pitch or F0 predictions as a function of which harmonics are being processed could be a result of resolved versus unresolved spectral structure and/or a difference in the ability of different channels to phase lock to the stimulus's fine structure (see Carlyon, R. P., 1998). This ambiguity prevents the original version of the summary correlogram model from accurately predicting F0 processing for some key conditions involving F0 processing as a function of harmonic number. Bernstein J. G. and Oxenham A. J. (2005) showed that a modification to the summary correlogram models (e.g., Meddis, R. and O'Mard, L., 1997) allowed them to account for F0 processing that depends on harmonic number.

Thus, at the present time temporal models especially autocorrelation-like models do a good job of accounting for the pitch of complex sounds, especially when the sounds do not contain low-frequency spectral components. However, as we will discuss later in the next section there are some new challenges to autocorrelation accounts of pitch processing.

3.47.13 Neural Processing of Pitch

A previous section (Section 3.47.4) on spectral and temporal processing of simple sounds summarized the pitch processing that is carried out in the auditory periphery. There are several lines of evidence that complex pitch processing is preformed centrally and

not peripherally. First, complex pitch requires a comparison of the spectral and/or temporal information across the spectrum of the sound. Thus, there has to be some form of spectral and/or temporal integration or comparison in order to account for the perceived complex pitch. Such comparisons or integration are likely to occur in neural centrals central to the periphery. There is also considerable evidence that complex pitch often involves stimulation to both ears. Since only neural centers above the cochlear nucleus receive bilateral input, such binaurally generated pitches must be generated at neural locations above the level of the cochlear nucleus. Houtsma A. J. M. and Goldstein J. L. (1972) were among the first to show that if different harmonics are presented to different ears, then the reported pitch is not that predicted by the harmonic structure at either ear, but on the combined harmonic structure from both ears (see Bernstein, J. G. and Oxenham, A. J., 2003 for a more recent version of this binaural work). That is, the harmonics from each ear must be combined centrally in order to account for the perceived pitch.

Several investigators (e.g., Cramer, E. M. and Huggins, W. H., 1958; Culling, J. F. *et al.*, 1998; Yost, W. A., 1991; Bilsen, F. A. and Raatgever, J., 2000) have also showed that reversing the phases of the spectral components of a noise in a narrow frequency band in one ear relative to the phases at the other ear produces a dichotic pitch (Huggins–Cramer pitch, Cramer, E. M. and Huggins, W. H., 1958) that is associated with the narrow spectral region over which the interaural phase shift exists. Again, such dichotic pitches require some form of integration of the information between the two ears.

While the neural site at which complex pitch is processed is likely central, several studies have investigated the type of information that the auditory periphery might provide to such a central processor. Cariani P. A. and Delgutte B. (1996a; 1996b) performed several experiments showing that if the central nervous system used a form of autocorrelation then the temporal information in the firings of auditory nerve fibers contained sufficient and necessary information for an autocorrelation-like process to determine the pitch for a wide variety of complex pitch stimuli used in perceptual experiments. Their analysis suggested that it was necessary to combine neural information across auditory nerve fibers tuned to a wide range of frequencies. They also argued that an analysis like an interval histogram in which the timing between only successive neural spikes is calculated could not adequately predict the data on complex pitch. Cedolin L. and Delgutte B. (2005) have also shown that at the level of the auditory nerve neither a temporal analysis nor a spectral/place analysis (based on the ability of the auditory nerve to resolve spectral structure) of auditory nerve data can completely account for a wide range of perceptual pitch data.

In these experiments and other uses of autocorrelation to study neural responses, the autocorrelation functions are computed as all-interval histograms. The interval between each successive neural spike is considered a first-order interval and these first-order intervals are the basis of the interval histogram often used in studying the temporal properties of neuronal function. A second-order interval is one between every other neural spike, third-order interval is that between every third spike, and an *n*th-order interval is that between every *n* spikes. Autocorrelation is equivalent to an all-order interval analysis. That is, an all-order interval histogram (the proportion of times that an interval of each possible duration occurred independent of the order of the interval) is an autocorrelation function.

Kaernbach C. and Demany L. (1998) have argued that the auditory system does not calculate an all-interval analysis (i.e., an autocorrelation analysis) because they and others (see Yost, W. A. *et al.*, 2005) have shown that the auditory system seems to be less sensitive to second-order intervals as compared to first-order intervals. An autocorrelation approach does not differentiate among interval order, i.e., all interval orders make the same contribution to the autocorrelation function. Thus, these results regarding a relative insensitivity to second-order intervals suggests that an auditory analysis might be autocorrelationlike, but is not actually autocorrelation. If such processes were biased toward lower-order intervals, they might perform better in accounting for some of the pitch data than an all-interval autocorrelation approach (see Pressnitzer, D. *et al.*, 2004). It is also the case that there is no physiological evidence for any auditory neural circuits that appear to be able to form an autocorrelation analysis (e.g., there is no evidence for a coincidence network as suggested by Licklider, J. C. R., 1951, when he proposed autocorrelation as a means to calculate pitch).

Several other investigators have shown that neural units of different types in the cochlear nucleus (e.g., Shofner, W. P., 1999; Winter, I. M. *et al.*, 2003) produce all-interval autocorrelation functions that are consistent with the pitch obtained in many perceptual experiments. In several of these experiments the

units that were studied were chopperlike cells that respond robustly to the envelope of complex sounds. This suggests that envelope fluctuations may play a role in complex pitch processing. As mentioned previously, several authors (see Schreiner, C. E. and Urbas, J. V., 1986; Langner, G. *et al.*, 1998) have suggested that neural centers in the inferior colliculus and cortex that appear to be tuned to the modulation rate of the envelope of complex sound may play a significant role in complex pitch processing.

While neural units that process the envelope of complex sounds may play some role in the processing of complex pitch, it is unlikely a complex sound's envelope is the necessary and sufficient process to account for complex pitch processing. Recall that the pitch-shift of the residue is different from the pitch of the residue itself. That is, the missing fundamental pitch is that of the fundamental, whereas when the spectral components are shifted up or down in value while keeping their component spacing constant, the pitch changes. Consider for example the case cited above in which for one condition the spectral components (spectral peaks) are at 400, 600, 800 Hz, etc. In this case the pitch of the residue or missing fundamental pitch is 200 Hz. If the spectral components are at 300, 500, 700, 900 Hz, etc. (i.e., shifted up by 100 Hz from the first case), the pitch-shift of the residue is either 100 Hz or plus or minus 10% of 200 Hz (180 and/or 220 Hz), but it is never 200 Hz. The temporal envelope of these two stimuli is the same (see Yost, W. A. *et al.*, 1998). That is, shifting the components by additive amount does not alter the temporal envelope of the sound. Since the pitch of such spectrally shifted complex stimuli does change as a function of the shift but their envelope does not, the envelope cannot be used to explain the pitch-shift of the residue. The predicted pitch-shift of the residue appears to depend on either the spectrum or the temporal fine structure of a complex sound, and not the envelope.

Up until recently research investigating the neural basis of pitch has depended on physiological data from animal models used to account for human pitch perception. Several investigators (see Shofner, W. P., 2005 for a review) have shown that the behavioral responses of several different animals to missing fundamental pitch stimuli appear to be similar to the ways in which human subjects respond to these same stimuli. Shofner W. P. *et al.* (2005) have shown in several different experiments that the behavioral responses of the Chinchilla to iterated rippled noise and other harmonic stimuli are very similar to the psychophysical data obtained from human subjects (See Chapter 5.44). However, recent data suggest that the Chinchilla is perhaps more sensitive to the envelope of complex pitch-producing sounds than are human subjects (Shofner, W. P. *et al.*, 2005). Thus, different animal subjects appear to process the pitch of complex sounds in ways that are similar to that of human subjects, suggesting that the neural measures obtained from animals are relevant for understanding the neural mechanisms that underlie pitch perception.

With the use of neural imaging (e.g., positron emission tomography, functional magnetic resonance imaging, magnetencephalography, and electroencephalography) it is possible to search for neural centers in human auditory pathways (especially in auditory cortex) that might play a role in pitch processing (See Chapter 3.50). In a series of studies, Heschl's Gyrus, in the human auditory cortex, has been implicated as a cortical region that is likely significantly involved with processing pitch and, perhaps, pitch that produce melodies (see Griffiths, T. D. *et al.*, 1998; Gutschalk, A., *et al.*, 2004; Seither-Preisler, A. *et al.*, 2004). The initial work used iterated ripple noise, but further studies suggest that many different stimuli that produce complex pitch are powerful in producing neural images that are consistent with the assumption the Heschl's Gyrus is participating in processing complex pitch. These data implicated temporal processing of complex pitch. Recently Wang and colleagues (Bendor, D. and Wang, X., 2005) have shown that in a neural region of the marmoset monkey that is homologous with Heschl's Gyrus in humans (only humans have a Heschl's Gyrus) multiunit and single-unit electrophysiological recordings also suggest that this cortical region plays a significant role in complex pitch processing. They used a wide variety of stimulus conditions producing converging data implicating this cortical region as participating in pitch processing. Current speculation is that the actual computation of pitch might occur in lower brainstem centers and that Heschl's Gyrus and its homolog in primates is a pathway that reads the output of such computations (Griffiths, T. D. *et al.*, 1998).

Thus, the study of complex pitch has a rich history. After more than 100 years it is still not clear exactly how complex pitch is processed. The current view appears to be that the most parsimonious way to account for complex pitch perception is with temporal models such as ones based on autocorrelation. However, the most salient complex pitches occur in

spectral regions where the spectral structure of the sounds are resolved by the auditory periphery and where a spectral account works as well as a temporal one. In addition, there are several studies that suggest that autocorrelation may not be the appropriate temporal model. The research on complex pitch and its neural basis continues at a rapid pace, and it will probably not take another 100 years for a single well establish theory to emerge.

Glossary

adaptation Change in response caused by prior or continuing stimulation. Sometimes adaptation is referred to as fatigue, which can be a misnomer because sensitivity can increase (e.g., dark adaptation) as well as decrease. Instead, adaptation is a process by which absolute sensitivity adjusts in a way to enhance sensitivity to change within a given dynamic range.

affricate consonants Speech sounds produced by a complete constriction of the vocal tract that is released into a very small opening such as that for a fricative.

allophonic variation Acoustic or phonetic variants of the same phoneme; discriminably different speech sounds that are identified as the same phoneme.

alveolar stops Stop consonants /t/ and /d/ which are produced by forming a complete constriction of the vocal tract at the alveolar ridge of the hard palate.

categorical perception The phenomenon in which stimuli that are made to vary continuously along one or more dimensions are perceived discretely, rather than continuously, as distinct classes. The hallmark of categorical perception is the finding that in discrimination tasks, two stimuli that have been given the same label in an identification task are discriminated at levels near chance, while two equidistant stimuli that have been given different labels are discriminated with almost perfect accuracy.

co-articulation Articulatory overlap of adjacent speech sounds which results in a blending of acoustic features across successive speech units.

color constancy The phenomenon that the perceived color of an object stays the same despite the fact that the actual wavelength of reflected light changes with changes in the ambient lighting.

contrast effects Refers to the perceptual enhancement of a stimulus attribute when paired in time and/or space with a stimulus attribute that is to a varying extent opposite or contrastive.

dental stops Stop consonants produced by forming a complete constriction of the vocal tract behind the teeth (like the fricative th in English) as in Hindi [d̪].

dynamic range The physical range over which the biological sensors operate effectively. The difference between the stimulus levels near threshold and those where the physiological response begins to saturate.

enhancement effect A decrease in threshold, or enhanced sensitivity, for a tone in a complex when preceded by a complex in which the tone is missing.

entropy Unpredictability, randomness; entropy is directly proportional to potential information and inversely proportional to redundancy (see Shannon information theory).

formants Peaks in the speech spectrum. Frequency locations of the formants, especially the first three, are important for identifying different speech sounds and depend on the vocal tract resonances, which vary with vocal tract length.

formant transitions Monotonically increasing or decreasing changes in the frequency locations of the formants, or vocal tract resonances, associated with movements of the articulators from one speech sound to another. Some important features of formant transitions that aid in the identification of speech sounds include their onset and offset frequencies and their rate of change.

fricative consonants Speech sounds characterized by a nearly complete constriction of the vocal tract that produces noise as turbulence is created by air passing through the small opening.

fundamental frequency The lowest frequency of a periodic signal. Distance in frequency between successive harmonics in voiced speech sounds corresponding to the rate of vocal fold vibration. The harmonic spectrum consists of the fundamental frequency (first harmonic) with higher harmonics at multiples of the fundamental.

information-theoretic See Shannon information theory.

inverse projection problem The fact that it is impossible to project a given physical stimulus (e.g., acoustic or optic) back to a determinate source because multiple sources can produce the exact same physical output.

lack of invariance (problem of variability) Refers to the fact that no one acoustic or articulatory feature is both necessary and sufficient to identify a given speech sound. The lack of a simple one-to-one correspondence between attributes of speech sounds and linguistic units such as phonemes is a problem only when classifying speech sounds, but not when perceiving them.

lateral inhibition When high neural activity at one frequency region causes a reduction in the neural activity at an adjacent frequency region. In this way, the edge between regions of contrast (high and low activity) is enhanced.

lexicon The morphemes and words comprising an individual's vocabulary.

liquid Sound category for /l/ and /r/ sounds, which are produced with vocal tract constrictions that are less than those for fricative and affricates but more than those for vowels.

manner of articulation A way of classifying consonant sounds that describes how the constrictions in the vocal tract are made when they are produced.

McGurk effect Phenomenon in which the auditory perception of a syllable is influenced by the simultaneous visual presentation of a conflicting syllable. This effect is dependent on auditory stimuli that are easily confused and visual stimuli (visemes) that are easily distinguished.

morpheme The smallest unit of language that carries meaning.

nasal consonants Speech sounds characterized by a complete constriction of the oral tract accompanied with a coupling of the nasal tract through which air flow is directed.
Necker cubes An optical illusion in which a two-dimensional cube is drawn in a way that causes ambiguity when it is perceived as a three-dimensional object. Two faces of the cube appear to be in front, but not at the same time. One's perception oscillates between the two equally plausible interpretations.
perceptual constancy Functional equivalence of discriminably different physical representations of the same object.
perceptrons Single-layer artificial neural network in which multiple weighted inputs are fed into a single binary output.
phonemes Abstract linguistic categories for speech sounds that are functionally equivalent, but not necessarily acoustically equivalent.
phonetic categories See phonemes.
phonetic segments Divisions of the acoustic speech signal corresponding to consonants and vowels.
phonotactic regularities Sequences of speech sounds that tend to co-occur in a language.
pink noise Noise with an energy distribution that decreases at a rate of −3 dB per octave as frequency increases, or a halving of energy with a doubling of frequency.
place of articulation A way of classifying consonant sounds that describes where in the vocal tract the constriction is made to produce them.
retroflex stops Stop consonants produced by forming a complete constriction of the vocal tract at the hard palate (like the liquid r in English) as in Hindi [ḍ].
Shannon information theory Claude Shannon's theory of communication in which information is represented as a mathematical entity that is agnostic with respect to meaning. The potential amount of information transmitted, or entropy, is related to the number of logarithmic units (e.g., bits) needed to uniquely code the communicated message. Fewer bits are needed when the context and a receiver's prior experience make certain elements of the message redundant.
spectral contrast Contrast effect (see definition) for the frequency composition of a sound. For example, a sound with a mid-frequency peak will be perceived as relatively higher in frequency when preceded by a sound with a lower-frequency peak and will be perceived as relatively lower in frequency when preceded by a sound with a higher-frequency peak.
spectral density The distribution of energy as a function of frequency.
stop consonants Speech sounds characterized by a complete constriction of the vocal tract that is held momentarily and then released in a more or less abrupt manner.
suppression The decrease in the physiological response to a particular frequency region when another, more intense, sound at a nearby frequency region is present.
trading relations Because humans have abundant experience hearing speech sounds that co-vary along multiple attributes, a change in one attribute toward one percept can be traded or offset by a change in another attribute toward the opposite percept.
voiced Speech sounds created with the vocal folds together and in vibration.
voiceless Speech sounds created with the vocal folds apart, hence not in vibration.

3.48.1 Introduction

During the second half of the twentieth century, research concerning speech perception stood relatively distinct from the study of audition and other modalities of high-level perception such as vision. Contemporary research, however, is beginning to bridge this traditional divide. Fundamental principles that govern all perception, some known for more than a century, are shaping our understanding of perception of speech as well as other familiar sounds.

The study of speech perception traditionally consisted of attempting to explain how listeners perceive the spoken acoustic signal as a sequence of consonants and vowels, collectively referred to as phonetic segments or units. When one describes speech sounds in this way, brackets are used to surround phonetic symbols such as [y] (as in yes) and [o] (as in oh). By contrast, phonemes are abstract linguistic units that roughly correspond to letters in written language, and are transcribed enclosed by slashes (/y/ and /o/.) Morphemes are the smallest meaningful units of language, roughly corresponding to words (e.g., dog,

taste, as well as dis- and -ful) with phonemes being the smallest units that can change the meaning of a morpheme (e.g., /yo/ vs. /go/) (Trubetzkoy, N. S., 1939/1969).

Conceptualizing speech perception as a process by which phonemes are retrieved from acoustic signals is the traditional approach. Within this tradition, research in speech perception often has been focused on problems concerning segmentation and lack of invariance. The problem of segmentation refers to the fact that, if phonetic units exist, they are not like typed letters on a page. Instead, they overlap extensively in time, much like cursive handwriting. The problem of lack of invariance (or, problem of variability) is related to the segmentation problem. Because speech sounds are produced such that articulations for one consonant or vowel overlaps with production of preceding ones, and vice versa, every consonant and vowel produced in fluent connected speech is dramatically colored by its neighbors. Some of the most recalcitrant problems in the study of speech perception are the consequence of adopting discrete phonetic segments as a level of perceptual analysis. However, phonetic segments may be neither discrete nor real.

No experimental evidence clearly demonstrates that either phonetic segments or phonemes are real outside of linguistic theory (e.g., Lotto, A. J., 2000), and the intuitive appeal of phonetic segments and phonemes may arise principally from experience with alphabetic writing systems (Port, R. F., in press). One ought not be sanguine about whether speech perception really is about recognizing consonants and vowels *per se*. It is not known whether or not listeners extract phonemes preliminary to recognizing words. There may or may not be some place in the brain where phonemes reside independent of the words they comprise.

Either morphemes or words may be the first units of language that stand more or less on their own accord. It is possible, even likely, that speech perception is a series of nondiscrete processes along the way from waveforms to words. In this chapter, speech perception will be described as a continuum of processes operating on the acoustic signal with varying levels of sophistication. The consistent theme will be common principles that define how these processes work.

Before explaining perception of speech, two preliminary topics need to be addressed. First, understanding perception always requires understanding the ecology within which perceptual systems operate. If one wishes to understand speech perception, at least some knowledge of speech production proves helpful. Second, because perception of speech adheres to the same principles that govern perception of other environmental objects and events, it will be helpful to briefly review some broad principles that govern perception most broadly.

3.48.2 Sounds Created with Ears in Mind

Speech and music are somewhat distinct from most other environmental sounds because, much like visual art such as paintings and sculpture, speech and music are created with perceivers in mind. Across hundreds of generations of humans, language users have found ways to use their lungs, larynx, and mouths to produce different sounds that can transmit a wealth of information to one another.

3.48.2.1 Speech Production

There are three basic components to production of speech: respiratory (lungs), phonatory (vocal chords), and articulatory (vocal tract). First is the respiratory system through which the diaphragm pushes air out of the lungs, through the trachea, and then the larynx. At the larynx, air must pass through the two vocal folds which are made up of muscle tissue that can be adjusted to vary how freely air passes through the opening between them. In some cases, such as voiceless sounds like [p] and [s], vocal folds are apart; they do not restrict airflow and do not vibrate. For voiced speech sounds like [b] and [z], vocal folds are closer together, and the pressure of airflow causes them to vibrate at the fundamental frequency (f_0). Owing to variations in the pressure of airflow from the lungs and muscular control of vocal fold tension, talkers can vary the fundamental frequency of voiced sounds. If one were to consider the nature of speech at this point, it could be depicted as a spectrum of energy spread across frequency and concentrated at the fundamental frequency and at multiples of the fundamental (i.e., a harmonic spectrum) with decreasing energy at each successive multiple as seen in Figure 1(a).

The area above the larynx, the oral tract and the nasal tract combined, is referred to as the vocal tract. The nearly continuously varying configuration of the vocal tract is responsible for shaping the spectrum

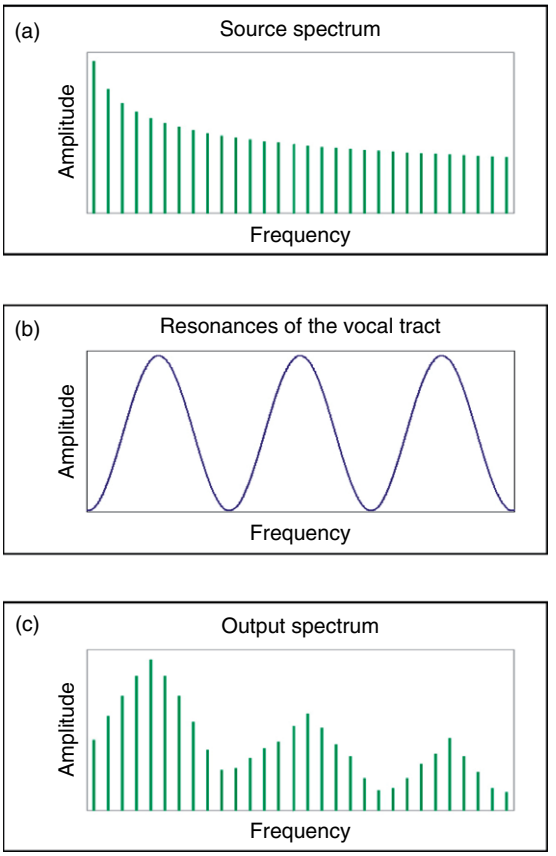

Figure 1 Harmonic spectrum of the laryngeal source (a) before passing through filtering properties (b) of the vocal tract resulting in the output spectrum with formant peaks (c).

differently for different speech sounds. There are many ways the jaw, lips, tongue body, tongue tip, velum (soft palate), and other vocal tract structures can be manipulated to shape the sounds that emanate from the mouth and nose. Widening and narrowing of points along the vocal tract selectively attenuate some frequencies while making others more prominent. Figure 1(b) illustrates the filtering effects of the vocal tract for the vowel [a] as in father. Figure 1(c) portrays the net result from passing the glottal source (a) through the vocal tract (b).

Peaks in the resultant spectrum are referred to as formants, described by number, lowest to highest (F_1, F_2, F_3,. . .). Only the first three formants are depicted in Figure 1, and for the most part, speech sounds can be identified on the basis of energy in the region of these lowest three formants. However, additional formants exist with lower amplitudes at higher frequencies (F_4, F_5, F_6, etc.), and are relatively more prominent in the speech of children.

Airflow can be channeled, constricted, or obstructed to produce different vowel and consonant sounds. Vowels are made with a relatively open unoccluded vocal tract. In terms of articulation, vowels vary mostly in how high or low and how forward (front) or back the tongue body is in the oral tract. In addition, some vowels are produced with rounded lips (e.g., [u] as in boot) or with modestly different fundamental frequencies among other variations.

In part because early linguists had greater access to their own vocal tracts than to sophisticated audio analysis, it is a general convention that speech sounds are described in terms of the articulations necessary to produce them. In addition to variation in tongue height, frontness/backness, and lip rounding as descriptions for vowels, consonants also are described by articulatory characteristics. For example, consonants are described in terms of the manner in which constrictions are introduced along the vocal tract. Stop consonants or plosives such as [b], [p], [d], [t], [g], and [k] include complete constriction such that no air may pass through. Nasal consonants such as [n], [m], and [ŋ] (as in sing) are like [b], [d], and [g], respectively, with complete constriction at some point in the oral tract, but air is allowed to escape through the nasal tract because the velum is lowered. Fricative consonants are caused by nearly complete obstruction of the vocal tract, with a noisy sound being produced by turbulence of airflow passing through a very small opening. Some examples of English fricatives are [s], [z], [š] (as in ash), and [ž] (as in azure.) Affricate consonants are produced by a combination of complete occlusion (like a stop) followed by nearly complete occlusion (like a fricative.) Examples of affricates in English are [č] (as in chug) and [ǰ] (as in jug.) The least constricted consonants in English are laterals and semivowels, such as [l], [w], [r], and [y].

Consonants also are described in terms of whether the vocal folds are close and vibrating, voiced, or further apart and not vibrating, voiceless. Thus, sounds such as [b], [d], [g], [z], [ž], [ǰ], [l], [w], [r], and [y] are voiced. And, [p], [t], [k], [s], [š], and [č] are voiceless. Finally, consonants are described on the basis of place of articulation. Constrictions can be placed along a number of places in the oral tract. In English, the three major places of articulation are bilabial (lips, [p], [b], [m]), alveolar (alveolar ridge behind teeth, [t], [d], [n]), and velar (soft palate or velum, [k], [g], [ŋ].)

3.48.2.2 Linguistic Sound Systems

The above description does not exhaust all the distinctions among the 40 or so sounds used in English, and it is a vast underdescription of variation among languages more generally. Owing primarily to unique characteristics of supralaryngeal anatomy (Lieberman, P., 1984), the adult human possesses sound-producing abilities unrivaled among other organisms. This capacity is revealed in a grand assortment of over 850 different speech sounds used contrastively by the more than 5000 distinct languages used around the world (Maddieson, I., 1984). There are more than 550 consonants and 300 vowels (including diphthongs such as [e^{y}] and [o^{y}], as in bay and boy). Such capacity dwarfs that of other animals, being more than an order of magnitude larger than the largest reported inventory of nonhuman primate calls (Cleveland, J. and Snowdon, C. T., 1982).

In contrast to this diversity in potential speech sounds, systematic inspection reveals that collections of consonants and vowels used by individual languages are anything but random. The vast majority of speech sounds are relatively rare, while a handful are extremely common. For example, all known languages have stop consonants. The overwhelming majority of languages have three places of articulation for stop consonants, typically the three described above for English. Over 80% of languages include a distinction in voicing (e.g., [p] vs. [b], [s] vs. [z]). Diversity does not imply randomness.

The structure of vowel systems is as much or more orderly than that for consonants. There is a fair amount of variety in the particular number of vowels used by languages. Some languages use as few as three vowels while others use as many as 24. English uses about 15 depending upon dialect. However, the most common number of vowels used by languages is only five, and other numbers of vowels appear to be relatively favored. Especially for the five- to nine-vowel systems that predominate across languages, particular sets of vowels are typically used. Figure 2 displays some of the more common three, five, and seven vowel systems. Although there are relatively fewer languages that use more than seven vowels, there remains a good deal of commonality among systems with the same number of vowels.

What are the forces acting upon languages that encourage the selection of some sounds and groups of sounds over others? Although the number of possible speech sounds is prodigious, one guiding factor explaining regularities is how easy some sounds are to produce either in isolation or in sequence with others. The role of articulatory ease is perhaps best evidenced by the fact that languages tend to use articulatorily simpler consonants before incorporating more complex consonants (Lindblom, B. and Maddieson, I., 1988).

Consistent with the close tethering of speech production and speech perception, languages have come to use sets of speech sounds that enhance perceptual effectiveness. Talkers expend effort for communicative robustness. For example, the tense high vowels [i] and [u] (as in beet and boot) require more effort to produce relative to their lax counterparts [I] and [U] (as in bit and book). The vowels [i] and [u], however, are acoustically more distinct, not only from each other, but also from other possible vowel sounds. And, across languages, these tense vowels [i] and [u] occur five times more frequently than lax vowels [I] and [U].

Common examples of talkers molding their utterances to the needs of the listener include instances in which conditions for communication are not optimal. Talkers speak more clearly to young or non-native listeners for whom distinctions are not obvious. When environments are noisy or reverberant, talkers strive to produce contrasts that are maximally distinctive. Most generally, speech sound repertoires of languages have developed over generations of individuals toward greater communicative effectiveness. Generations of talkers have come to capitalize upon auditory predispositions of listeners.

An obvious way that a language community achieves such robustness is by developing an inventory of phonemes so as to optimize distinctiveness acoustically and auditorily. Inspection of regularities in vowel sounds used by languages, such as those shown in Figure 2 provides some of the most illuminating examples of auditory processes operating as a driving force. Different languages use different sets of vowel sounds, and languages use subsets of vowels that are most easily discriminated from one another. In particular, those vowels favored for languages with five vowels are vowels that are as acoustically distant as possible from one another. As a general rule, the set of vowels selected by a language, whether it uses three or ten vowels, is comprised of sounds that tend toward maximal distinctiveness (Bladon, R. A. W. and Lindblom, B., 1981; Liljencrantz, J. and Lindblom, B., 1972).

There is another way that differences between speech sounds are perceptually more dependable. Every consonant and vowel is defined by multiple acoustic properties. For example, the distinction between [b] and [p] as in rabid and rapid includes

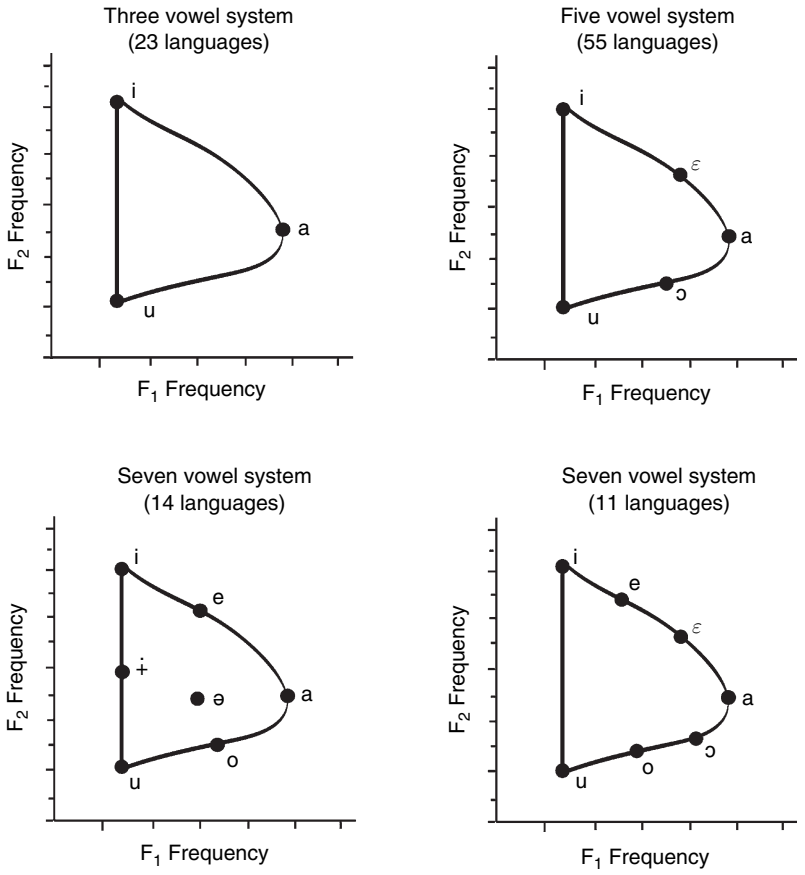

Figure 2 Common three-, five-, and seven-vowel systems used around the world as depicted in frequencies of first and second formants. Note that languages tend to use sets of vowels that are as acoustically distinct as possible within the range of vocal tract limits (solid lines.)

at least 16 different acoustic differences (Lisker, L., 1978). Further, no single acoustic attribute from these 16 is necessary to signal the distinction. Much of this redundancy in speech sounds results from the complexity of speech signal, a consequence of the fact that the structures that produce speech, the larynx and vocal tract, also are complex. Talkers morph their vocal tracts into widely varying shapes with different lengths. The surfaces inside vocal tracts vary considerably from tooth enamel to fleshy lips and soft palate, resulting in wildly varying absorption and reflection properties throughout the length of the vocal tract. Talkers produce multiple acoustic cues in a fashion that makes differences between speech sounds more perceptible (Kingston, J. and Diehl, R. L., 1994; Kluender, K. R., 1994) resulting in yet greater redundancy in the acoustic signal.

Languages have developed to be robust signaling systems, and distinctions between speech sounds do not rely upon the ability to make fine-grained discriminations bordering on thresholds of auditory systems. In this way, perception of speech bears little likeness to classic psychophysical studies of absolute thresholds and just-noticeable differences. Hearing the differences between vowels like [æ] (as in bat) and [ɛ] (as in bet), on the basis of gross spectral differences, shares little in common with psychoacoustic studies that demonstrate humans' abilities to detect changes as small as 1 Hz from a 1000 Hz sinusoid tone.

Because languages use distinctions that maximize acoustic differences and exploit auditory capacities, several observations follow. First, human infants are quite proficient at discriminating differences between speech sounds from a very early age. Three decades of studies document the impressive abilities of human infants, some less than 1 week old, to discriminate a wide variety of consonants and vowels from

across many languages (see, e.g., Jusczyk, P. W., 1981). A plethora of positive findings indicate that infants have the discriminative capacity necessary for most or all of the speech distinctions they will need to use in their language. Languages tend to use distinctions that are relatively easy to detect, and infant auditory abilities appear to be quite well developed. By 3 months of age, the human auditory system is nearly adult-like in absolute sensitivity and frequency-resolving power within the frequency range of most speech sounds (e.g., Olsho, L. W. et *al.*, 1988; 1987; Werner, L. and Gillenwater, J., 1990; Chapter Human Auditory Development).

A second observation, perhaps more telling than the first, is that discrimination of speech contrasts by nonhuman animals appears to be generally quite good. There have been a fair number of demonstrations that animals can distinguish human speech sounds with facility (see, e.g., Kluender, K. R. *et al.*, 2005). Differences between vowel sounds present no apparent difficulty for nonhuman animals. Several species have been shown to distinguish voiced from voiceless stop consonants, or to distinguish consonants on the basis of place of articulation (even beyond the basic three places described for English above). Such findings are expected on the basis of languages tending to use distinctions that are relatively easy to discriminate.

3.48.3 Some Fundamentals of Perception

To mostly ill effect, for many years much of speech perception was studied in relative isolation from the study of perception more generally. In part, this state of affairs was encouraged by the focus of language researchers (linguists and psycholinguists) seeking to know more about elemental aspects of language use. Consistent with focus on apparently unique characteristics of human language, early speech researchers were encouraged to believe that perception of speech might be as unique as language itself. For this and other historical reasons, research in speech perception was often naïve to developments in related areas of perception.

3.48.3.1 The Inverse Problem

An enduring distraction for investigators studying speech perception has concerned the extent to which articulatory gestures (e.g., Fowler, C. A., 1986; Liberman, A. M. and Mattingly, I. G., 1985), acoustic patterns, patterns of sensory stimulation (e.g., Diehl, R. L. and Kluender, K. R., 1989), or some combination (e.g., Nearey, T. M., 1997; Stevens, K. N. and Blumstein, S. E., 1981) serve as proper objects of speech perception. Controversies concerning appropriate objects of perception generated more heat than light. However, debates concerning objects of perception cannot be resolved because the question itself is ill-posed, if not outright misleading. There are no objects of perception, neither for speech nor for perception in general. There is an objective for perception, which is to maintain adequate agreement between an organism and its world in order to facilitate adaptive behavior. Success with this objective does not require objects of perception.

Within this functional framework, perceptual success does not require recovery or representations of the world *per se*. Perceivers' subjective impressions may be of objects and events in the world, and the study of perceptual processes may lead to inspection of real-world objects and events, patterns of light or sound pressure waves, transduction properties, or neural responses. By and large, however, viewing perception with a focus toward either distal or proximal properties falls short of capturing the essential functional characteristic of perception – the relationship between an organism's environment and its actions.

Much work in perception has been concerned, in one way or another, with addressing the inverse problem. The inverse problem emerges from the simple fact that information available to sensory transducers (eyes, ears, etc.) is inadequate to authentically reconstruct a unique distal state of affairs. In vision, for any two-dimensional projection, there are an infinite number of possible three-dimensional objects that could give rise to exactly the same two-dimensional (2D) retinal image (Figure 3). In audition, for any sound-pressure wave, there are an infinite number of sound producing events that could give rise to that waveform. One telling example of the difficulty of mapping from acoustics to a sound-producing event is the case of attempting to solve the inverse from waveform to simpler 2D surfaces (e.g., the shape of a drum.). Mathematicians have formally proved that even this relatively simple translation from waveform to plane geometry is impossible (Gordon, C. *et al.*, 1992).

Because multiple sound sources yield the same waveform, waveforms can never be more complex than characteristics of physical sources. Researchers within the field of speech perception have long been

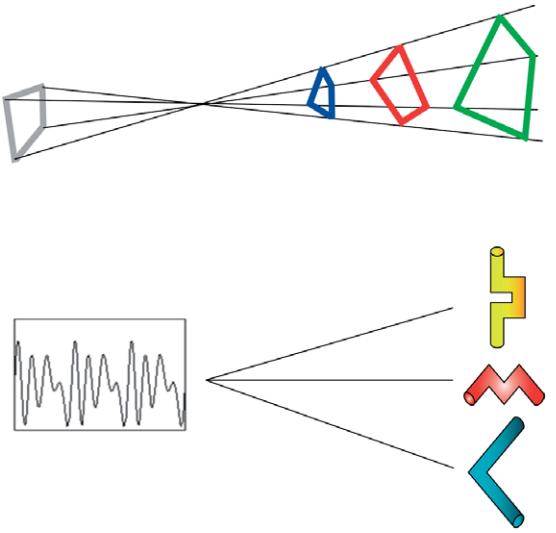

Figure 3 An infinite number of external three-dimensional objects give rise to the same two-dimensional retinal image (top, left). An infinite number of sound producing sources (characterized here as resonator shapes) give rise to the same waveform available to the ear.

familiar with appeals to perception via articulatory gestures as a simplifying construct, and there have been a series of efforts to extract gestures in order to facilitate machine speech recognition, albeit with very limited success. What physics demands, however, is that depiction of speech in terms of articulatory gestures gives only the illusion of simplicity. Because scientists are much better at measuring details of sounds than they are at measuring details of articulator activity, articulatory gestures appear simpler only because they are defined more abstractly and are measured with less precision. Because multiple resonator configurations can give rise to the same waveform, the acoustic waveform available to listeners is always less variable than articulation.

For all of the discussion that follows regarding specific issues concerning speech perception, speech typically will be described as sounds. This is not because sounds are legitimate objects of perception, but rather because, along the chain of events from creating patterns of sound pressure to encoding these patterns in some collection of neural firings to eliciting behavior, waveforms are public, easily measurable, and simpler than alternatives.

3.48.3.2 Why Perception Seems Veridical

If perceiving the true state of the world is impossible, one might ask why phenomenal experience is not fuzzy and uncertain. To effectively guide behavior and not leave the organism pondering multiple possibilities, all that is required is that the perceptual system comes to the same adaptive output every time it receives the same functional input. It is this deterministic nature of perception that prevents paralysis within a sea of alternatives. Phenomenal experience of certain reality does not depend upon authentic rendering of the world. Instead, phenomenal experience of a clear and certain world is the consequence of perceptual systems reliably arriving at deterministically unique outputs. It is this reliability that encourages certainty (Hume, D., 1748/1963), but reliability is not validity.

On rare occasions, perceptual systems do not converge upon a unique output and are left oscillating between equally fitting outputs when sensory inputs are not singly determinate (usually in response to impoverished stimuli.) Many readers are familiar with bistability when viewing Necker cubes. One such auditory experience is encountered when listening to a repeating synthesized syllable intermediate between [da] and [ta] or any other pair of similar speech sounds. When two perceptual outputs fit the input equally well, phenomenal experience oscillates between each percept (Tuller, B. *et al.*, 1994).

3.48.3.3 Information for Perception

If there are no objects of perception, how should one think about information for perception? Information for perception does not exist in the objects and events in the world, nor does it exist in the head of the perceiver. Instead, information exists in the relationship between an organism and its world. It may be useful to consider the contrast between information about and information for. When one discusses objects of perception, it is information about that is typically inferred. Implicit in such efforts is the notion that one needs to solve the inverse problem. By contrast, if the objective of a successful perceptual system is to maintain adequate agreement between an organism and its world in order to facilitate adaptive behavior, then information for successful perception is nothing more or less than information that resides in this relationship (or agreement).

This way of viewing information as a relationship is consistent with one of the fundamental characteristics of Shannon's information theory (Shannon, C. E., 1948; Weiner, N., 1948). Some readers may be familiar with Fletcher's pioneering applications of information theory to speech (Fletcher, H., 1953/1995). However,

the application here will be more akin to the approach of Attneave F. (1954; 1959) and Barlow H. B. (1961) for vision, an approach that remains highly productive (e.g., Barlow, H. B., 1997; 2001; Simoncelli, E. P. and Olshausen, B. A., 2001; Schwartz, O. and Simoncelli, E. P., 2001). One important point of Shannon's information theory is that information exists only in the relationship between transmitters and receivers; information does not exist in either *per se*, and it does not portray any essential characteristics about either transmitters or receivers. Within this information-theoretic sense, perceptual information exists in the relationship between organisms and their environments. This is the objective of perception.

Within a sea of alternative perceptual endpoints, agreement between the organism and environment aims to establish the alternative that gives rise to the most adaptive behavior. Information is transmitted when uncertainty is reduced and agreement is achieved between organism and environment. The greater the number of alternatives (uncertainty, unpredictability, variability, or entropy) there are, the greater the amount of information that potentially can be transmitted (see Figure 4(a)). There is no information when there is no variability. When there is no variability, there is total predictability and hence, no information transmitted. There is much that stays the same in the world from time to time and place to place, but there is no information in stasis. Uncertainty is reduced consequent to the perceiver's current experience (context) as well as past experiences with the environment (learning).

Although the amount of theoretical potential information transmitted is maximized at maximum entropy (total unpredictability or randomness), it is not advantageous for biological systems to shift their dynamic range as far as possible toward this maximum. In natural environments, this would result in diminishing returns if the system adjusts to register the last bits of near-random energy flux. Instead, biological systems should maximize the efficiency with which they capture information relative to the distribution of energy flux in real environments. The best estimate of statistics of natural environments is $1/f$(pink) noise (Figure 4(b)). This simple power law with a negative exponent (f^1)is scale-invariant, and it is a ubiquitous characteristic across many systems from radioactive decay to fluid dynamics, biological systems, and astronomy. As one would expect, spectral density of fluctuations in acoustic power of music and speech varies as $1/f$ (Voss, R. F. and Clarke, J.,

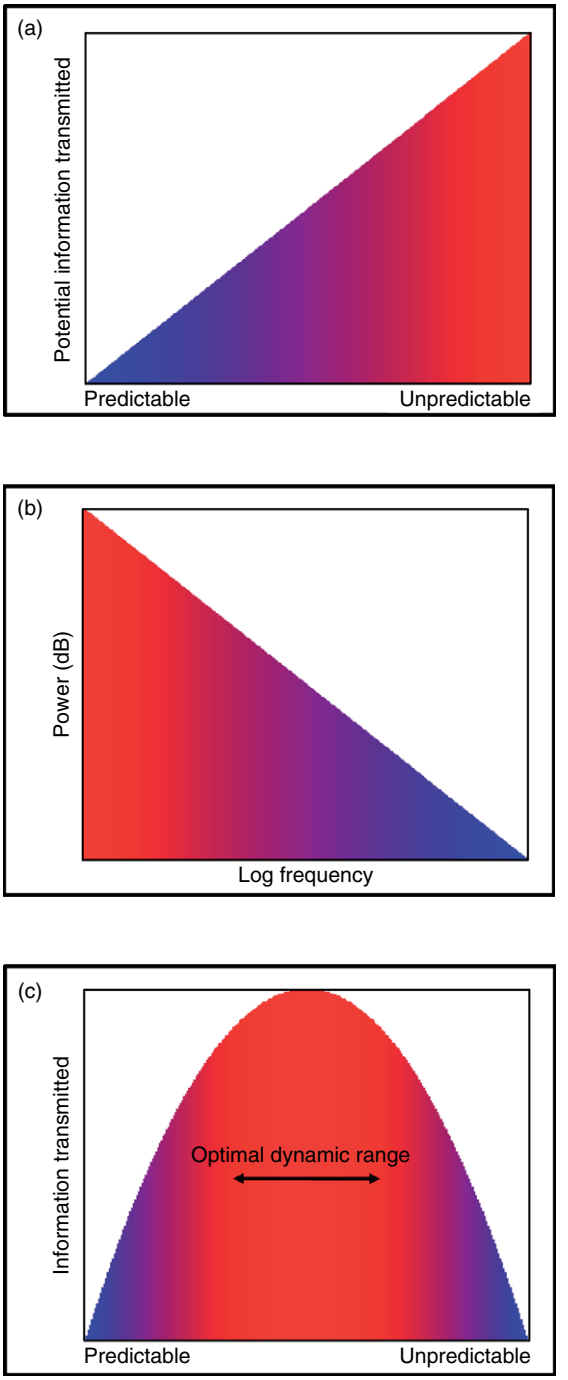

Figure 4 The greater the number of alternatives (uncertainty, unpredictability, variability, or entropy) there are, the greater the amount of information that potentially can be transmitted (a). There is no new information in what stays the same or is predictable. Relative power of energy flux in natural environments approximates 1/*f* (b). Information transmission optimized relative to energy flux in the environment (c). An ideal sensori-neural system should center dynamic range about this maximum.

1975; 1978.) Efficient information transmission for sensori-neural systems with limited dynamic range may be depicted best as the product of the positive exponential growth in information and the negative exponential of $1/f$. This yields the quadratic function shown in Figure 4(c) describing optimal transmission of information relative to energy flux in the environment.

3.48.3.4 Sensory Systems Respond to Change (and Little Else)

Given these facts about information, it is true and fortunate that sensori-neural systems operate as they do. Sensori-neural systems respond only to change relative to what is predictable or does not change. Perceptual systems do not record absolute levels whether loudness, pitch, brightness, or color. Relative change is the coin of the realm for perception, a fact known at least since Ernst Weber in the mid-eighteenth century. This has been demonstrated perceptually in every sensory domain. Humans have a remarkable ability to make fine discriminations, or relative judgments, about frequency and intensity. The number of discriminations than can be made numbers in the hundreds or thousands before full dynamic range is exhausted. Yet, most humans are capable of reliably categorizing, or making absolute judgments about only a relatively small number of stimuli regardless of physical dimension (e.g., Gardner, W.R. and Hake, H. W. 1951; Miller, G. A., 1956).

Sacrifice of absolute encoding has enormous benefits along the way to optimizing information transmission. Although biological sensors have impressive dynamic range given their evolution via borrowed parts (e.g., gill arches to middle ear bones), this dynamic range is always a fraction of the physical range of absolute levels available from the environment and essential to organisms' survival. This is true whether one is considering optical luminance or acoustic pressure. The beauty of sensory systems is that, by responding to relative change, a limited dynamic range shifts upward and downward to optimize the amount of change that can be detected in the environment at a given moment.

The simplest way that sensory systems adjust dynamic range to optimize sensitivity is via processes of adaptation. Following nothing, even a subtle sensory stimulus can trigger a strong sensation. However, when a level of sensory input is sustained over time, constant stimulation loses impact. This sort of sensory attenuation due to adaptation is ubiquitous, and has been documented in vision (Riggs, L. A. *et al.*, 1953), audition (Hood, J. D., 1950), taste (Urbantschitsch, V. 1876, cf. Abrahams, H., *et. al.*, 1937), touch (Hoagland, H., 1933), and smell (Zwaardemaker, H., 1895, Engen, T., 1982). It is not uncommon to find instances where the terms adaptation and fatigue are used interchangeably. However, this equivocation is inappropriate. Consider, for example, visual dark adaptation whereby sensitivity to light is increased. Adaptation is a process whereby dynamic range adjusts, upward or downward, to maximize sensitivity to change. There are increasingly sophisticated mechanisms supporting sensitivity to change with ascending levels of processing, and several will be discussed in this chapter. Most important for now is the fundamental principle that perception of any object or event is always relative – critically dependent on its context.

3.48.4 Contrast and Low-Level Speech Perception

3.48.4.1 Contrast in General

Because it is only change that is perceived, perception at any particular time or place always depends on temporally or spatially adjacent information. Many instances of sensitivity to change are revealed through demonstration of contrast. For example, as depicted in Figure 5, a gray region appears darker against a white background and lighter next to a black background (see, e.g., Anderson, B. L. and Winawer, J., 2005). While examples abound for all modalities, sensory contrast has been most amply demonstrated in studies of visual perception, with contrast being a fundamental process that reveals edges of objects and surfaces.

Contrast effects are ubiquitous, and of course, they exist for audition (Cathcart, E. P. and Dawson, S, 1928/1929; Christman, R. J., 1954). Forms of auditory contrast are important for several aspects of speech perception. Over the past few years, multiple studies have provided evidence that simple processes of spectral contrast contribute to solving one of the most, if not the most, difficult questions concerning speech perception, co-articulated speech. Co-articulation is the spatial and temporal overlap of adjacent articulatory activities, and it is reflected in the acoustic signal by severe context dependence. Acoustic information specifying one speech sound varies substantially depending on surrounding sounds.

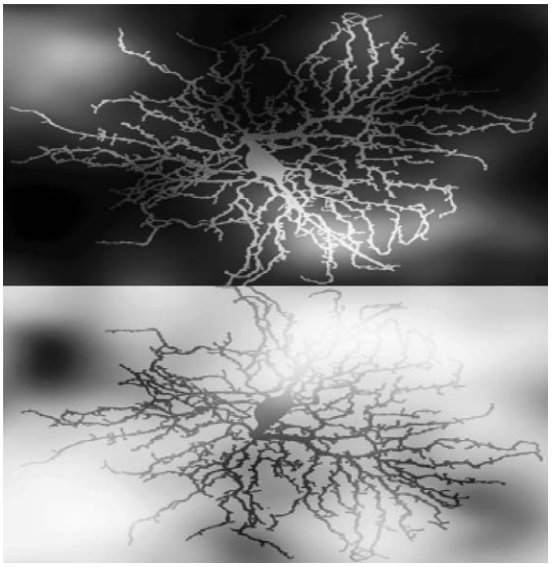

Figure 5 Contrast effects are ubiquitous in perception. For this example of lightness contrast, absolute lightness/darkness of these mirror-image neurons is identical.

3.48.4.2 Contrast and Perception of Co-Articulated Speech

The problem for speech perception is how listeners hear a speech sound such as [d] when acoustic characteristics change dramatically depending upon sounds that precede and follow (e.g., vowels [e] versus [o]) (see Figure 6). Co-articulation presents a major challenge to automatic speech recognition (ASR) systems, which largely identify speech sounds on the basis of matching stored templates. Instead of storing a single template for [d], multiple templates must be stored for [d] following all other possible speech sounds, and each of those templates must be stored multiply for every instance of [d] preceding all other possible speech sounds. For ASR, this strategy using a geometrically expanding set of templates can be made to work so long as one has sufficient memory and sufficient processing speed to sort through templates. Not surprisingly, progress in ASR over decades is closely correlated with speed of microprocessors and price of memory (Lippman, R. P., 1996).

There is a consistent pattern to co-articulation that suggests a simpler solution. Adjacent sounds always assimilate toward the spectral characteristics of one another. Owing to mass and inertia of articulators (as well as planning), articulatory movements are compromises between where articulators have been and where they are headed. Because the acoustic signal directly reflects these articulatory facts, the frequency spectrum assimilates in the same fashion that speech articulation assimilates.

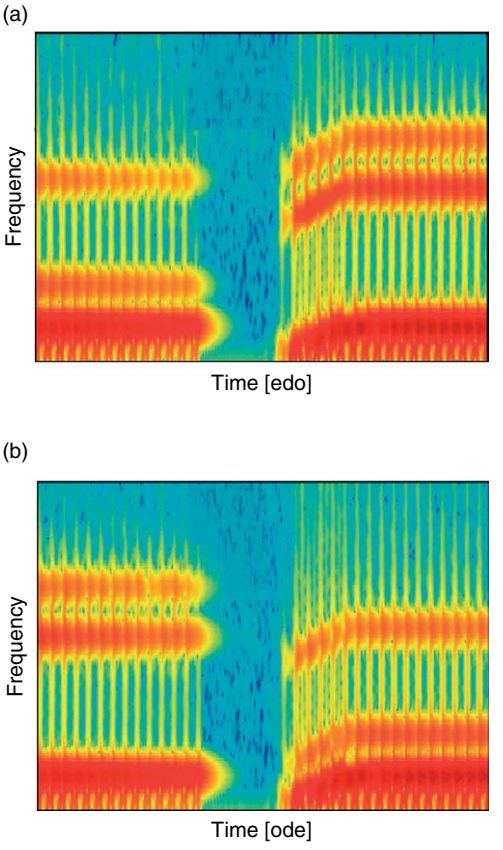

Figure 6 Schematic spectrograms of [edo] (a) and [ode] (b) Note that acoustic properties of [d] depend upon characteristics of preceding and following vowel sounds.

Lindblom B. E. F. (1963) provided some of the best early evidence concerning how context systematically influences speech production. He reported that the frequency of the second formant (F_2) was higher in the productions of [dId] (did) and [dUd] (dud) than for the vowels [ɪ] and [ʊ] in isolation, and that F_2 was lower for vowels in [bIb] and [bUb]. In both contexts, F_2 frequency approached that of flanking consonants, which are higher for [d] than for [b]. In a subsequent study, Lindblom B. E. F and Studdert-Kennedy M. (1967) demonstrated that perception of co-articulated vowels is complementary to these facts of articulation. Listeners reported hearing /ɪ/ (higher F_2) more often in [wVw] (lower F_2) context, and /ʊ/ more often in [jVj] (higher F_2) context. Consonant context affected vowel perception in a manner complementary to the assimilative effects of co-articulation. Lindblom B. E. F. and Studdert-Kennedy M. (1967) wrote: "It is worth reiterating. . .that mechanisms of perceptual analysis

whose operations contribute to *enhancing contrast* in the above-mentioned sense are precisely the type of mechanisms that seem well suited to their purpose given the fact that the slurred and sluggish manner in which human speech sound stimuli are often generated tends to reduce rather than sharpen contrast. (p. 842, italics added)"

One of the most thoroughly investigated cases for perceptual context dependence concerns the realization of [d] and [g] as a function of preceding liquid (Mann, V. A., 1980) or fricative (Mann, V. A. and Repp, B. H., 1981). Perception of /d/ as contrasted with perception of /g/, can be largely signaled by the onset frequency and trajectory of the third formant (F_3). In the context of a following [a], a higher F_3 onset encourages perception of /da/ while a lower F_3 onset results in perception of /ga/. Onset frequency of the F_3 transition varies as a function of the preceding consonant in connected speech. For example, F_3-onset frequency for [da] is higher following [al] in [alda] than when following [ar] in [arda]. The offset frequency of F_3 is higher for [al] owing to a more forward place of articulation, and is lower for [ar].

Perception of /da/ and /ga/ has been shown to be complementary to the facts of production much as it is for CVCs. Listeners are more likely to report hearing /da/ (high F_3) when preceded by the syllable [ar] (low F_3), and hearing /ga/ (low F_3) when preceded by [al] (high F_3) (Mann, V. A., 1980; Lotto, A. J. and Kluender, K. R., 1998). In subsequent studies, the effect has been found for speakers of Japanese who cannot distinguish [l] and [r] (Mann, V. A., 1986), for prelinguistic infants (Fowler, C. A. *et al.*, 1990), and for avian subjects (Lotto, A. J. *et al.*, 1997.) The same pattern of findings has been replicated for perception of /d/ and /g/ following fricatives [š] and [ʃ] such that listeners are more likely to report hearing /d/ (high F_3) following [ʃ] (lower-frequency noise) and hearing /g/ (low F_3) following [š] (higher-frequency noise) (Mann, V. A. and Repp, B. H., 1981).

Co-articulation *per se* can be dissociated from its acoustic consequences by combining synthetic speech targets with nonspeech flanking energy that captures minimal essential spectral aspects of speech. Lotto A. J. and Kluender K. R. (1998) replaced [al] and [ar] precursors with nothing more than constant-frequency sinusoids set to the offset frequencies of F_3 for [al] and [ar] syllables. Perception of following [da-ga] shifted just as it did following full-spectrum [al] and [ar] (Figure 7).

Holt L. L., *et al.*, (2000) replicated the Lindblom and Studdert-Kennedy findings (1967) with CVCs using the vowels [ɛ] and [ʌ] flanked by stop consonants [b] and [d]. They replaced flanking [b] and [d] with FM glides that tracked the center frequency of only F_2 for [b] or [d]. Again, the pattern of results for flanking nonspeech FM glides mimicked that for full-spectrum [b] and [d] syllable-initial and syllable-final transitions. Based upon the results for VCCVs (Lotto, A. J. and Kluender, K. R., 1998) and these results for CVCs, one can conclude that much of perceptual accommodation for co-articulation is not restricted to speech-like signals. All of the findings are consistent with spectral contrast, whereby the spectral composition of context serves to diminish or enhance the perceptual efficacy of spectral components for adjacent sounds.

In keeping with typical usage, the term contrast has been used in a largely descriptive way thus far. There are a large number of experimental precedents for spectral contrast – often called auditory enhancement, and these precedents provide more specific hypotheses. Summerfield Q. *et al.* (1984) established the existence of

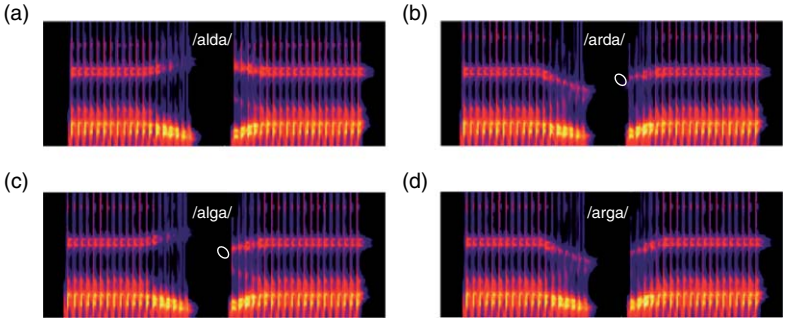

Figure 7 Due to co-articulation, acoustic properties of any speech sound become more similar to the properties of sounds preceding and following. This assimilation is a property of all fluent connected speech. Here, acoustic characteristics of [d] (e.g., F_3, marked by ellipse) following [r] are very similar to those of [g] following [l]. Listeners hear the same consonant vowel (CV) as /d/ following [ar] and as /g/ following [al].

an aftereffect in vowel perception. When a uniform harmonic spectrum was preceded by a spectrum that was complementary to a particular vowel with troughs replacing peaks and vice versa, listeners reported hearing a vowel during presentation of the uniform spectrum. The vowel percept (for the uniform spectrum) was appropriate for a spectrum with peaks at frequencies where there were troughs in the preceding spectrum.

Summerfield Q. *et al.* (1984) noted that perceiving vowel sounds in uniform spectra (following appropriate complementary spectral patterns) has a well-known precedent in psychoacoustics. This oft-reported finding is that, if just one member of a set of harmonics of equal amplitude is omitted from a harmonic series and is reintroduced, then it stands out perceptually against the background of the preexisting harmonics (Schouten, J. F., 1940; Green, D. M. *et al.*, 1959; Cardozo, B. L., 1967; Viemeister, N. F., 1980; Houtgast, T., 1972). Viemeister (1980), for example, demonstrated that the threshold for detecting a tone in a harmonic complex is 10–12 dB lower when the incomplete harmonic complex (missing the target tone) precedes the tone as compared to when the onset of the inharmonic complex is coincident with that for the target tone. This was referred to as an enhancement effect. Viemeister N. F. (1980) then examined a number of properties of this effect, finding that the complex need not be harmonic and that noise maskers or bandpass noise signals also served to enhance the detection of the tone. He also found the effect over a wide range of intensities for maskers and targets.

Summerfield Q. *et al.* (1984; 1987) suggested that their demonstration of vowel aftereffects may be rooted in peripheral sensory adaptation. One could suggest that neurons adapt, and the prominence of the added harmonic is due to the fact that neurons tuned to its frequency were not adapted prior to its onset. Alternatively, some researchers (e.g., Houtgast, T., 1974; Moore, B. C. J. and Glasberg, B. R., 1983) have suggested that rapid adaptation serves mostly to enhance onsets selectively, with suppression being a process through which differences in level of adjacent spectral regions in complex spectra (e.g., formants in speech signals) are preserved and/or enhanced.

Viemeister N. F. and Bacon S. P. (1982) showed that, not only was an enhanced target tone more detectable, the tone also served as a more effective masker of a following tone. They suggested that suppression must be included in an adaptation scenario to place it in closer accord to this finding. Different frequency components of a signal serve to suppress one another, and two-tone suppression has been cast as an instance of lateral inhibition in hearing (Houtgast, T., 1972). Investigators have argued that suppression helps to provide sharp tuning (e.g., Wightman, F. L. *et al.*, 1977; Festen, J. M. and Plomp, R., 1981), and with respect to speech perception, Houtgast T. (1974) has argued that this process serves to sharpen the neural projection of a vowel spectrum in a fashion that enhances spectral peaks.

Many neurophysiological observations bear upon enhancement effects. In particular, a number of neurophysiological studies of auditory nerve (AN) recordings (e.g., Smith, R. L. and Zwislocki, J. J., 1971; Smith, R. L., 1979; Smith, R. L. *et al.*, 1985) strongly imply a role for peripheral adaptation. Delgutte and colleagues (Delgutte, B., 1980; 1986; 1996; Delgutte, B. *et al.*, 1996; Delgutte, B. and Kiang, N. Y. S., 1984) have established the case for a much broader role of peripheral adaptation in perception of speech. Delgutte notes that peaks in AN discharge rate correspond to spectro-temporal regions that are rich in phonetic information, and that adaptation increases the resolution with which onsets are represented. He also notes neurophysiological evidence that "adaptation enhances *spectral contrast* between successive speech segments" (Delgutte, B. *et al.*, 1996, p. 3, italics added). This enhancement arises because a fiber adapted by stimulus components close to its CF is relatively less responsive to subsequent energy at that frequency, while stimulus components not present immediately prior are encoded by fibers that are unadapted – essentially the same process offered by psychoacousticians but now grounded in physiology. In addition, Delgutte notes that adaptation takes place on many timescales, and is sustained longer with increasing level in the auditory system.

Inspired by the vowel aftereffect studies by Summerfield Q. *et al.* (1984; 1987), Coady J. A. *et al.*, (2003) sought to make clearer the connections between experiments using very simple nonspeech flanking stimuli (e.g., FM glides) and Summerfield's studies using rich spectra that were complementary to those for vowel sounds. Although sine waves and FM glides have often been used as nonspeech proxies for formants, such sounds have limited resemblance to speech formants. While it is true that spectrograms illustrate formants as bands of energy, and formant transitions as bands of energy traversing frequency, such descriptions can be misleading. For example, if fundamental frequency (f_0) is constant, individual harmonics of the fundamental do not change frequency at all, and all that changes are relative amplitudes of

harmonics. Individual frequency components of the speech spectrum change frequency no more than f_0 changes.

Coady J. A. *et al.* (2003) used VCV sequences for which the initial vowel ([e] or [o]) affects perception of the following consonant (/ba/ or /da/). In addition to creating synthetic vowels [e] and [o], they created spectral complements of these vowels [∼e] and [∼o] by creating troughs where formants occurred for [e] and [o]. These precursor vowel-complements altered perception in a fashion opposite that of normal (non-complement) vowels because troughs in energy increased excitability within a frequency range for which excitability was attenuated when a frequency prominence (formant) was present in a normal vowel. In addition, they demonstrated that these perceptual effects relied substantially upon spectral characteristics of onsets.

It appears that the same underlying processes account for effects of both very simple nonspeech precursors and spectrally rich vowel-like complements. Although more complex or domain-limited theories of speech perception have been proposed to explain perception of co-articulated speech, the above patterns of perception with both simple and complex stimuli suggest that spectral contrast is an important part of the explanation for perceptual accommodation of co-articulated speech.

3.48.4.3 Broader Spectral and Temporal Effects

Contributions of spectral contrast to perception of co-articulated speech are narrowly focused in both time and frequency. Processes through which the auditory system optimizes detection of spectral change operate over durations on the order of less than 0.5 s, and spectral components of interest are relatively local (e.g., formants.) In keeping with the fundamental principle that, in the interest of maximizing transmission of new information, perceptual systems respond primarily to change, long-term signal characteristics that do not change should also alter perception in similar ways.

For vision, perceivers maintain color constancy in the face of changes in level or spectral composition of illumination, respectively. The visual system adjusts for the spectral composition of illumination (e.g., sunlight versus tungsten or fluorescent lighting), while maintaining relatively consistent perception of color under widely varying viewing conditions. Analogous challenges arise for hearing. When auditory experiments are conducted in the laboratory, experimenters typically endeavor to maintain consistent response across all frequencies through the use of high-quality audio equipment and headphones. However, in real-world listening environments, the spectrum is virtually always colored by characteristics of the listening environment. Energy at some frequencies is reinforced by reflective properties of surfaces, while energy at other frequencies is dampened by absorption properties of materials and shapes of objects in the environment. For hearing to be most effective, listeners must adapt to reliable spectral characteristics in order to be maximally sensitive to the most informative characteristics of sounds.

Kiefte M. and Kluender K. R. (in press) used vowel sounds to examine how auditory systems may adapt to predictable (redundant) spectral characteristics of the acoustic context in order to be more sensitive to information-bearing characteristics of sounds. Simple vowel sounds are useful in this application because it is known that listeners use both spectrally narrow (formant peaks) and broad properties (gross spectral tilt) to perceive vowel sounds. For example, low frequency F1 is heard as /u/ (as in boot) when accompanied by a low frequency F2, and as /i/ (as in beet) when accompanied by higher frequency F_2. In addition, gross spectral tilt, the relative balance between low- and high-frequency energy, is quite different for these vowels. The vowel [u] has more low- than high-frequency energy, resulting in a gross spectral tilt of rapidly declining energy as a function of increasing frequency. In contrast, [i] has relatively more high-frequency energy, and energy decreases much more gradually with increasing frequency. When listening to isolated vowel sounds, listeners use a combination of both formant frequencies and gross spectral tilt to identify vowels (Kiefte, M. and Kluender, K. R., 2005).

Kiefte and Kluender created a matrix of vowel stimuli that varied perceptually from /u/ to /i/ in two dimensions: center frequency of F_2 and gross spectral tilt. Along one dimension, center frequency of F_2 varied from low ([u]) to high ([i]). Along the second dimension, gross spectral tilt varied in the same stepwise fashion, from a spectral tilt characteristic of [u] to one characteristic of [i]. Listeners identified this matrix of vowel sounds preceded by a synthesized rendition of the sentence "You will now hear the vowel. . ." When long-term spectral tilt of context sentences was altered to match that of the following vowel, listeners relied virtually exclusively upon the frequency of F_2 when identifying /i/ and /u/. This pattern of performance indicates that tilt, as a predictable spectral property of

acoustic context, was effectively canceled out of perception (Figure 8).

Encoding of predictable characteristics such as spectral tilt requires only the most abstract characterization of the spectrum, with little spectral detail. Changes in spectral tilt can be due to changes in acoustic properties of the physical environment, or particular to speech, changes in emotional state or speaker identity (Klatt, D. H., 1982). Neither of these properties change rapidly and both are relatively stable across time relative to the rapid spectral changes found in speech. Kiefte and Kluender then tested whether perception also compensates for local spectral properties when these properties are stable across time.

Using the same sentence context, sentences were processed with a single-pole filter which corresponded exactly to the frequency and bandwidth of F_2 of the target, yielding intact sentences with an additional constant-frequency spectral peak added throughout. When presented with a stimulus in which F_2 was an unchanging acoustic property of the context, listeners relied largely upon global spectral characteristics (tilt) for identification of the target vowel. Effects of preceding context are not restricted to gross spectral properties. Perceptual cancellation of predictable spectral characteristics also occurs for local, relatively narrowband spectral characteristics of the acoustic context.

Perceptual cancellation of predictable acoustic context does not depend upon preceding context being speech (Holt, L. L., 2005; Stilp, C. and Kluender, K. R., 2006), nor does it depend upon the context being identical trial to trial (Kiefte, M. and Kluender, K. R., in press). Listener performance provides evidence that the auditory system is quite adept at factoring out predictable characteristics of a listening context, and is consequently more sensitive to informative changes in spectral composition across time.

Underlying mechanisms by which the auditory system calibrates for characteristics of acoustic context have not yet been extensively investigated, and are not yet understood. Some primary auditory cortex (AI) neurons encode spectral shape with respect to both broad and narrow complex spectral shapes (Barbour, D. L. and Wang, X., 2003), and neurons in AI are sensitive to the relative probabilities of pure tones of different frequencies in an extended sequence of tones (Ulanovsky, N. *et al.*, 2003). Calibrating to acoustic context in the service of enhancing sensitivity to change would have been efficacious since the very first auditory systems, even before the advent of

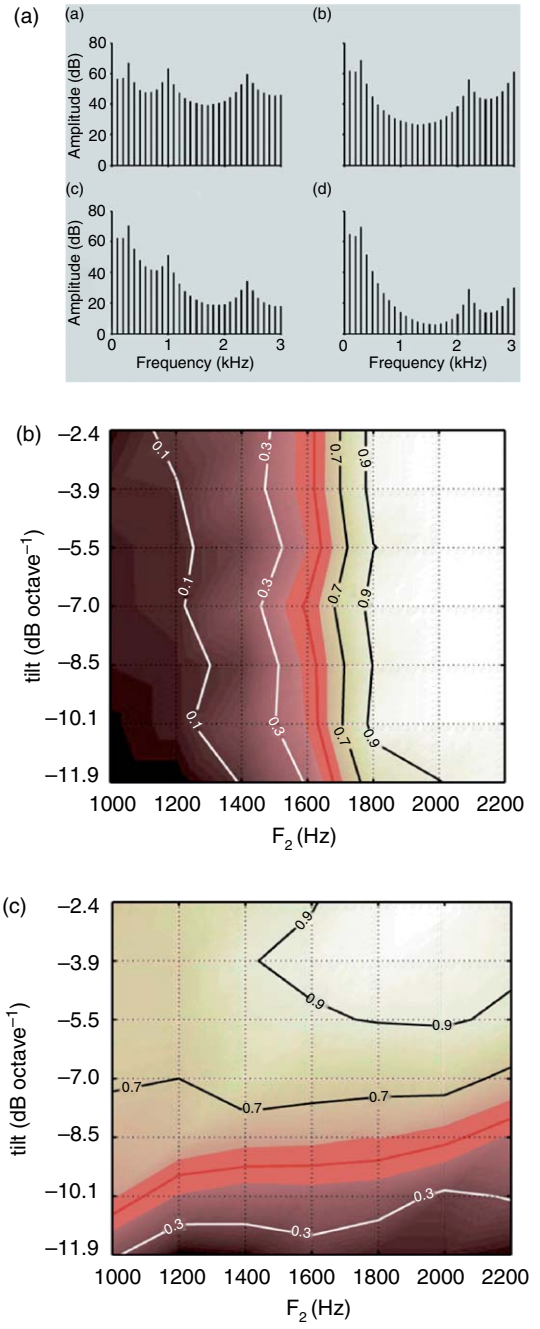

Figure 8 Spectra of vowel sounds [u] and [i] vary both in center frequency of F_2 and overall spectral tilt, and listeners use both acoustic properties to identify these vowels. Kiefte M. and Kluender K. R. (in press) created sounds that varied in each dimension independently (a). When listeners heard these vowel sounds following a precursor that was filtered to have the same spectral tilt as a target vowel, listeners used F_2 frequency exclusively when identifying the vowels (b). The complementary pattern of results, exclusive use of tilt, obtains when precursors include a constant-frequency spectral peak matching F_2 of the target sound (c).

neocortex. It is possible, or perhaps likely, that brainstem processes play an important role.

Projections from superior olive to outer hair cells, collectively called the medial olivocochlear (MOC) efferent system have been hypothesized to provide adjustments of basilar membrane tuning to improve resolution of signals against background noise. Kirk E. C. and Smith D. W. (2003), for example, hypothesized the MOC evolved as a mechanism for unmasking biologically significant acoustic stimuli. A few synapses further from the cochlea, inferior colliculus (IC) neurons adapt to structural regularities in natural sounds in a fashion that increases information transmission (Escabi, M. A. *et al.*, 2003), and stimulus specific adaptation much like that found by Ulanovsky N. *et al.* (2003) also has been demonstrated in IC (Pérez-González, D. *et al.*, 2005).

3.48.5 Maximizing Transmission of Speech Information with Multiple Dimensions

3.48.5.1 Speech Perception Uses Multiple Sources of Information

A signature property of speech perception is its extreme resilience in the face of dramatic signal degradation. For example, listeners understand speech at signal-to-noise ratios less than 0 dB, and they understand speech either when all energy is removed above 1500 Hz or when all energy is removed below 1500 Hz. Listeners can understand speech when the only information available is fluctuations in amplitude of eight or so bands of noise across frequency (Shannon, R. V. *et al.*, 1995), and some listeners can understand speech consisting of little more than sine waves that track the center frequencies of formants (Remez, R. E. *et al.*, 1981). In large part, these as well as other demonstrations of perceptual resilience can be explained by the fact that listeners can rely upon experience with speech that far exceeds experience with any other type of sounds. This power of experience rests upon the high degree of redundancy within the speech signal.

Experience with redundancy is among the reasons why performance of listeners detecting tones in quiet or detecting differences in pitch between two tones are rather poor predictors of the ability of the same listeners to understand speech. Listeners who suffer significant hearing loss can, nonetheless, manage to understand speech until the level of impairment becomes severe or there is substantial background noise competing with the speech signal. Profoundly deaf people who have received cochlear prosthetics (electrodes implanted into the cochlea) and who consequently receive extremely degraded signal via as few as one–four electrode contacts, nevertheless, can often understand speech, sometimes sufficiently well to talk on the telephone.

Redundancy does not distinguish speech from other objects and events in the world. For example, Attneave F. (1954) notes that information received by the visual system is redundant with sensory events that are highly interdependent in both space and time, and this is simply because "the world as we know it is lawful." (p. 183). Because multiple attributes are used when perceiving speech, the presence of one attribute can compensate for the absence of another, as increasing the magnitude of one source of information serves to compensate for decrease of another. There have been many demonstrations of these trading relations (e.g., Repp, B. H., 1982).

Using multiple stimulus attributes is common to perception across modalities. For example, multiple monocular and binocular cues contribute to visual perception of distance. While individual neurons rarely provide high fidelity, populations of neurons acting in concert robustly encode information even when signals are substantially degraded. Implicit to population encoding is the fact that relationships between activities of multiple neurons conspire for effective perception. It is the correlation of activity across neurons (i.e., redundancy) that makes sensorineural systems robust. Exploiting correlations among multiple attributes in speech perception provides another example of maximizing the performance of perceptual systems by extracting predictability in the service of emphasizing change. The quintessential example of combining multiple acoustic attributes is categorical perception (Figure 9).

Although rarely recognized as being so (Kluender, K. R., 1988; 1994), perceptual constancy and categorization share a great deal in common. A classic definition of categorization is that it permits treating discriminably different examples as functionally equivalent. A virtue of categorization typically is presented as efficiently directing responses to functionally equivalent objects or events. Similarly, perceptual constancy maintains when discriminably different exposures (varying with size, orientation, etc.) are treated as equivalent. For example, the apparent size of an object remains the same even when brought nearer or farther from the perceiver. And, perceived shape stays the same across rotations. The simple observation that nonhuman

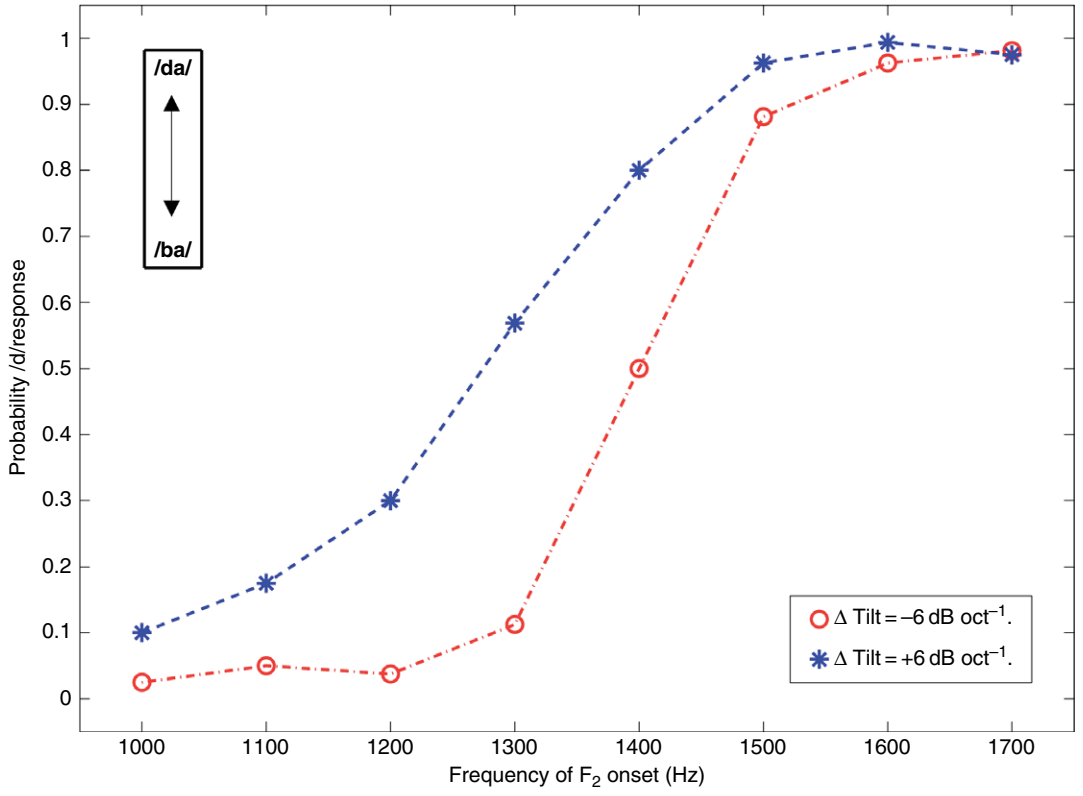

Figure 9 Listeners' use of multiple acoustic attributes is commonly demonstrated by experiments in which two attributes are independently manipulated. In this example from Alexander J. M. and Kluender K. R. (2005), when relative spectral tilt is positive (blue), listeners hear sounds with lower F_2 onset frequency as /d/. One attributes trades against another, as more of one compensates for less of another.

animals manage to navigate their worlds is ample testimony to their ability to maintain perceptual constancy. Nonhuman animals also have been shown to categorize both visual images and acoustic stimuli such as speech (Herrnstein, R. J., 1984; Kluender, K. R. *et al.*, 1987).

Confusion between perceptual constancy and perceptual categorization is common in descriptions of speech perception as somehow arriving at appropriate phonetic categories. However, there have been a fair number of instances for which researchers adopted perceptual constancy as the preferred description (see, e.g., Kuhl, P. K., 1978; 1979; 1980; 1987). Here it is proposed that categorical perception be thought of as perceptual constancy. To the extent that categorization is only a more abstract manifestation of constancy, choosing constancy may not be a particularly provocative choice. If one considers perception of speech to involve perceptual constancy, commonalities with similar perceptual achievements are revealed and surplus cognitive content typically ascribed to categorization is avoided.

3.48.5.2 Categorical Perception

Categorical perception is the most well-known pattern of perceptual performance with speech sounds. Three features define categorical perception: a sharp labeling (identification) function, discontinuous discrimination performance (near-perfect across identification boundary and near-chance to either side), and the ability to predict discrimination performance purely on the basis of labeling data (Wood, C. C., 1976). All three defining features of categorical perception arise naturally from the principle of discovering (and perceptually absorbing) predictability in the interest of maximizing sensitivity to change.

Returning to the fact that speech sounds are comprised of multiple acoustic attributes, many of which are redundant, one acoustic attribute serves to predict the occurrence of another. Through experience, perceptual processes come to absorb these correlations in a way that increases efficiency. There is no information in predictability. When perceptual systems encode correlations among attributes, there are

two consequences. First, there is a decrease in sensitivity to differences between two sounds that share the same pattern of correlation among the same set of attributes. Second, two sounds with different patterns of correlation become easier to distinguish. For speech, detection of differences between functionally different speech sounds is optimized to the extent that perceptual processes absorb redundancies across acoustic attributes that co-vary as properties of the same consonant or vowel (Figure 10).

3.48.5.2.1 Principal components analysis: an analogy

This perceptual processing can be compared with the statistical technique principal component analysis (PCA; see, e.g., Dillon, W. R. and Goldstein, M., 1984). For PCA, one begins with a correlation matrix of multiple variables, created to assess the degree to which each variable is correlated with every other variable across many observations. From this correlation matrix, it is possible to determine weighted combinations of variables, vectors, which account for as much shared variance as possible. To the extent that multiple observations reveal covariance among variables, a limited number of vectors (few relative to the number of variables) can account for a high percentage of the total variance across observations.

PCA is being used here only as analogy because it is unlikely that real neurons adhere to formal restrictions on how vectors are chosen, and the ways PCA fails as analogy are themselves illuminating. First, PCA is a linear analysis, and it is well-known that sensory processes are nonlinear. Second, PCA assumes normally distributed values, and the real world complies with this assumption only to varying extents. A related analysis, independent component analysis (ICA; see, e.g., Hyvärinen, A. and Oja, E., 2000) does permit violations of assumption of normality, and may come a bit closer to modeling neural processing. Third, PCA, but not networks of neurons, requires that vectors be ordered from most to least amount of variance accounted for, and these vectors must be uncorrelated (eigenvectors).

The issue concerning orthogonality is interesting in two ways. First, while perfect efficiency is achieved if every vector shares no variance with any other vector, achieving this goal is unlikely in a neural system. A second point is more informative. Here, perception is being construed as a cascade of processes, each working to extract redundancy from the outputs of earlier processes. To the extent that outputs of prior processes even approach orthogonality, this would seem to imply

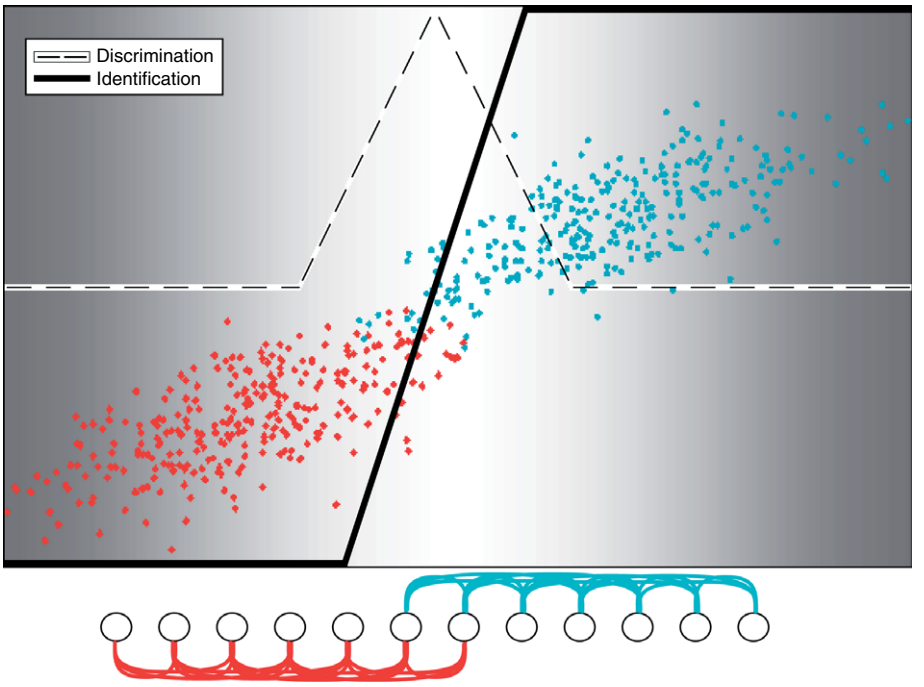

Figure 10 Categorical perception can be explained by auditory systems treating sounds with attributes that share the same correlation structure as equivalent. By this explanation, detection of differences between two complex sounds is greatest when each sound corresponds to a different pattern of experienced correlation.

that seizing upon correlation again would become increasingly implausible. The solution to this seeming dead end is that, with every successive reduction of redundancy, information over which processing operates expands in space, frequency, time, and any other dimension of interest. Thus, statistical relationships that hold relatively locally do not constrain correlations at the next coarser grain of processing. It is worthwhile to note the parallels between this statistical analogy and hierarchical organization of perceptual processing in the central nervous system.

Finally, there is a parallel between practical use of PCA and the prior argument that perceptual systems should efficiently optimize, not maximize, information transmission. Figure 4(c) depicts a sensori-neural system tuned to focus dynamic range in a way that optimizes information transmission relative to the distribution $(1/f)$ of energy flux in the environment while neglecting the last bits of potential information. At an extreme, PCA also permits characterization of all of the variance across observations when the number of eigenvectors is equal to the number of observations. However, the virtue of PCA is that the majority of, but not all, variance can be accounted for by relatively few vectors. Efficiencies are gained by capturing correlations within a few vectors. More eigenvectors are discarded than are saved, despite the fact that some snippets of information are lost.

From the analogy to PCA, it is easy to envision efficient sensori-neural encoding that extracts reliable correlations between multiple attributes across observations. This process can be instantiated in perceptrons (Rosenblat, F., 1958), the simplest connectionist networks. Most important to the analogy is that experience is encoded efficiently in a way that decreases sensitivity to differences between stimulus inputs that share the same correlation vector (or attractor) and increases sensitivity to differences between inputs that correspond to different vectors (see, e.g., Olshausen, B. A. and Field, D. J., 1997; Simoncelli, E. P. and Olshausen, B. A., 2001).

3.48.5.2.2 Phonemes as correlations?

Through experience with redundant attributes, simplified encoding of inputs as patterns of correlation serves as grist for consequent processing. It could be argued that vectors in a correlation matrix correspond to the putative linguistic units called phonemes (Kluender, K. R. and Lotto, A. J., 1999); however, the same basic principles apply continuously along the chain of processing, and such a demarcation would be artificial. The grain of synthesis steadily increases, from attributes that are spectrally and temporally local to those that extend across multiple attributes derived from preceding processing through to lexical organization. For example, Kingston J. and Diehl R. L. (1994) hypothesized intermediate perceptual properties (IPPs) may correspond to earlier analysis, and it is likely that statistical properties of acoustically simpler vowel and consonant sounds are extracted prior to those for more complex speech sounds. Further, as described below, additional reification of phoneme-like dimensions may await lexical organization.

Perhaps, no real harm may be done if one suggests that some correlations are phonemes *per se*, if only as a placeholder. However, it is important to distinguish two ways of thinking about this. The first way is common or even typical. One could suggest that the task for a listener is to identify consonants and vowels as individual psychological entities, and those entities are represented by correlations among attributes.

The second way, suggested here, is that consonants and vowels are revealed much more by what they are not than by what they are. Contrasts between sounds, not commonalities, are emphasized in speech perception. Through experience, perceptual processes become especially sensitive to acoustic differences that distinguish different consonants and vowels as a consequence ignoring differences among multiple acoustic properties that share a history of co-occurrence. What matters are distinctions between speech sounds, which are enhanced perceptually, not consonants and vowels themselves. Listeners hear the sounds of a language by virtue of learning how they are distinguished from all other consonants and vowels. This idea was most explicitly expressed by linguists Roman Jacobson and Morris Halle in their classic book *Fundamentals of Language* (1971) "All phonemes denote nothing but mere otherness" (p. 22).

3.48.5.2.3 Categorical perception as competing correlations

Returning to categorical perception, one can understand how these patterns of performance emerge naturally from perceptual systems exploiting redundancies among attributes in the service of maximizing sensitivity to change. Following experience with correlations among acoustic attributes, listeners are relatively unlikely to detect differences among complex sounds that share the same correlation structure. The fact that modest changes are perceptually neglected is consistent with the fact that listeners can understand speech when some acoustic properties

(e.g., energy above 1500 Hz) are absent. When the correlation structure is not violated too severely, perception overcomes perturbations, and even absence, of some attributes that normally contribute to the correlation. All that is required are sufficient attributes to get to the right vector.

This lack of sensitivity to perturbations among inputs accounts for the finding that discrimination performance is near chance for different instances of the same consonant or vowel. If two different stimuli fit the same correlation structure relatively well, the same perceptual consequences obtain. Complementary to this lack of discrimination for sounds that share the same correlation structure, discrimination performance is exquisite when the speech sounds to be discriminated are associated with two competing correlation structures. For these cases, discrimination is especially good because, by virtue of perceptual processes extracting redundancies within separate correlation structures, detection of change (information transmission) is optimized.

If categorical perception is only another example of perceptual constancy operating within general principles of perceptual organization, why did so many researchers believe categorical perception to be unusual? One reason is because categorical perception was routinely contrasted with psychophysical data from experiments employing very simple stimuli (typically unidimensional) of limited ecological significance. Equally important, comparisons were made to stimuli with which subjects have little or no experience before coming to the experimental session. Classic psychoacoustic experiments using pure tones, noise bursts, and inharmonic complexes have great utility for interrogating operating characteristics of sensory transduction absent content or experience. Thresholds for energy detection or sensory change are valuable things to know, but these are not as informative with respect to perception as it guides real activities in a real world.

When investigators use stimuli that are complex and familiar, signature response patterns of categorical perception are found. Categorical perception has been reported for musical intervals (Burns, E. M. and Ward, W. D. 1974; 1978; Smith, J. D. *et al.*, 1994) and tempered triads (Locke, S. and Kellar, L., 1973). Visually, humans categorically perceive human faces (Beale, J. M. and Keil, F. C., 1995) and facial expressions (Etcoff, N. L. and Magee, J. J., 1992; Calder, A. J. *et al.*, 1996; de Gelder, B. *et al.*, 1997; Young, A. W. *et al.*, 1997), as well as faces of different species (Campbell, R. *et al.*, 1997). When human observers are trained with artificial categories, they demonstrate increased perceptual sensitivity for items that are categorized differently (Goldstone, R. L., 1994). When monkeys are trained to respond differentially to clear examples of cats versus dogs (initially novel categories for monkeys), behavioral responses to stimuli along a morphed cat/dog series exhibit sharp crossovers at the series midpoint (Freedman, D. J. *et al.*, 2001). Rather than being specific to speech, categorical perception is a general property of any perceptual system consequent to experience with rich regularities of natural objects and events.

Categorical perception appears to be an emergent property of any perceptual system that is shaped by experience. Damper R. I. and Harnad S. R. (2000) reviewed evidence from human and animal listeners as well as from neural network models. They concluded that any number of generalized learning mechanisms can account for categorical perception. Models ranging from simple associative networks (e.g., Anderson, J. A., *et al.*, 1977) to back-propagation networks with no hidden units (e.g., Damper, R. I. *et al.*, 2000) exhibit categorical perception. Because categorical performance arises from a variety of simple learning algorithms that seize upon reliable statistics in their inputs, Damper R. I. and Harnad S. R. (2000) conclude that specialized processing is not necessary, and that "any general learning system operating on broadly neural principles ought to exhibit the essentials of [categorical perception]" (p. 862).

3.48.5.2.4 Multimodal interactions are expected

Thus far, and for the remainder of this contribution, discussion typically will be restricted to auditory perception of speech. This should not be taken to imply that other modalities do not contribute to understanding speech. The approach outlined here is explicitly associationist and driven by experience. The brain is opportunistic. Sensorineural systems seize upon redundancies to maximize information transmission whenever possible. Contemporary research (e.g., Bahrick, L.E. *et al.*, 2004) reveals how intersensory redundancy guides development of perception most generally. Whenever nonauditory information is redundant with speech acoustics, those correlations should contribute to efficient encoding of speech. For example, listeners have a wealth of experience simultaneously hearing speech and viewing talkers' faces, and the McGurk effect (McGurk, H. and MacDonald, J., 1976) is evidence of the profound effects visual information can have on the way speech sounds are perceived. Also, whenever people are

talking, they both hear the sounds they're producing and they experience the movements in their own vocal tracts. While ideally, this occurs less than half the time people hear speech, simultaneous activities of both hearing and talking provide exquisite conditions for extraction of correlations.

3.48.6 Experience and Sound Contrasts in the Native Language

Experience is essential for the development of every sensori-neural system. The profound role of experience is especially clear for speech perception. Infants gain significant experience with speech even before they're born. Late-term fetuses can discriminate vowel sounds (Lecanuet, J. P. *et al.*, 1986), and prenatal experience with speech sounds appears to have considerable influence on subsequent perception, as newborns prefer hearing their mother's voice (DeCasper, A., and Fifer, W., 1980). By the time French infants are 4 days old, they discriminate French from other languages (e.g., Russian) (Mehler, J. *et al.*, 1988). Perhaps most telling is the finding that newborns prefer hearing particular children's stories that were read aloud by their mothers during the third trimester (DeCasper, A. J. and Spence, M. J., 1986).

Experience plays a critical role in tuning speech perception to the distributions of sounds within one's language environment. Much, if not most, of this development as a native listener takes place during the first year of life. One of the most challenging obstacles for the infant is to use acoustic information that distinguishes one speech sound from another in the face of sometimes widely varying acoustic properties, many of which do not distinguish speech sounds in their language. Acoustic differences that convey a contrast in one language may be of little or no relevance to another language. Some of these differences simply may be unrelated (orthogonal) to distinctions used in a particular language and would not occur in a language context. In addition, clearly audible differences such as gender of talker, speaking rate, emotional state, and other factors have profound effects on the acoustic signal, yet the language learner must learn to understand speech across these variations.

3.48.6.1 Vowels

At least by the age of 6 months, infants have the ability to distinguish stimuli by vowel type even when different instances of the vowel differ considerably between presentations (Kuhl, P. K., 1983). In a reinforced head turn paradigm, Kuhl trained infants to turn their heads only when the vowel of the background stimulus changed during presentation of the closely related vowels [a] (as in tot) and [ɔ] (as in taught) spoken by a male talker. When tested on novel vowels produced by women and children (adding random variation in pitch contour in addition to shifting absolute frequencies of formants), infants provided the correct response on the first trial demonstrating that they recognized the novel instances as consistent with training vowels despite talker changes. Note that, by the shared covariance account offered above, the capacity to distinguish vowels across variation in irrelevant acoustic characteristics is a natural consequence of encoding stimuli on the basis of attributes that tend to co-occur. Attributes such as those accompanying changes in talker are irrelevant to particular consonants and vowels, so they do not play much role in phonetic distinctions.

While these studies attest to the ability of infants to respond to distinctions between vowels in the face of irrelevant variation, later studies have investigated how perception may be structured along acoustic/auditory dimensions that are directly relevant to distinguishing vowel sounds. What has become most apparent is that the degree to which infants treat acoustically different instances of the same vowel as equivalent is critically dependent upon their experience with a particular language. For example, 6-month-old infants detect differences between vowel sounds differently depending upon whether they lived in an English-speaking (Seattle) or Swedish-speaking (Stockholm) home (Kuhl, P. K., *et al.*, 1992).

Further evidence for the role of experience can be found in experiments in which performance by European starlings (*Sturnus vulgaris*), having learned statistically controlled distributions of renditions of Swedish and English vowels, was highly correlated with performance of adult human listeners (Kluender, K. R. *et al.*,1998). A simple linear association network model, exposed to the same vowels heard by the birds, accounted for 95% of the variance in avian responses. Consistent with the principle that consonants and vowels are defined mostly be what sounds they are not, both human goodness judgments (Lively, S. E., 1993) and starling response rates illustrate an anisotropy such that peak responses are skewed away from competing vowel sounds more than they are defined by centroids of vowel distributions.

3.48.6.2 Consonants

Perception of differences between consonants is similarly tuned by experience. Werkerand her colleagues (Werker, J. F. *et al*., 1981; Werker, J. F. and Logan, J. S., 1985; Werker, J. F. and Lalonde, C. E., 1988; Werker, J. F. and Tees, R. C., 1983, 1984a; 1984b) have demonstrated that, as a consequence of experience with consonants in their native language, infants' tendency to respond to differences between some consonants that are not in their language begins to attenuate. The series of studies by Werker J. F. and Lalonde C. E. (1988) permit a relatively complete description of the phenomena. They exploited the fact that speakers of English and Hindi use place of articulation somewhat differently for stop consonants. While for English, three places of articulation are used for voiced stop consonants: labial, alveolar, and velar (e.g. /b/, /d̪/, and /g/, respectively), in Hindi four places are used: labial, dental, retroflex, and velar (e.g. /b/, /d̪/, /ḍ/, and /g/, respectively.) They created a synthetic series that varied perceptually from /b/ to /d/ (for native-English speaking adults) and from /b/ to /d̪/ to /ḍ/ (for native-Hindi speaking adults) (Figure 11).

Using the same reinforced head turn procedure used by Kuhl, they found that 6- to 8-month-old infants from English-speaking families responded to changes in stimulus tokens that crossed perceptually from the English /b/ to /ḍ/ and also responded to changes between Hindi stops [d̪] and [ḍ]. A different group of infants from English speaking families aged 11- to 13-months of age responded reliably only to the English [b]-[d̪] contrast, and not to the Hindi [d̪]-[ḍ] contrast. Essentially, 6- to 8-month-old infants responded in a manner typical of native-Hindi adults, while 11- to 13-month-olds responded like native-English adults treating both dental and retroflex stops as being the same. Werker and her colleagues have found analogous results in studies using different consonant contrasts from different languages.

For vowels and consonants, perception of speech is shaped during the first year of life in ways that respect the statistics of the linguistic environment. The challenge for the infant learning the speech sound distinctions in his or her native language is precisely this. Infants must learn how acoustic/auditory attributes tend to co-occur, and those correlations among attributes define perceptual organization that optimizes sensitivity to change.

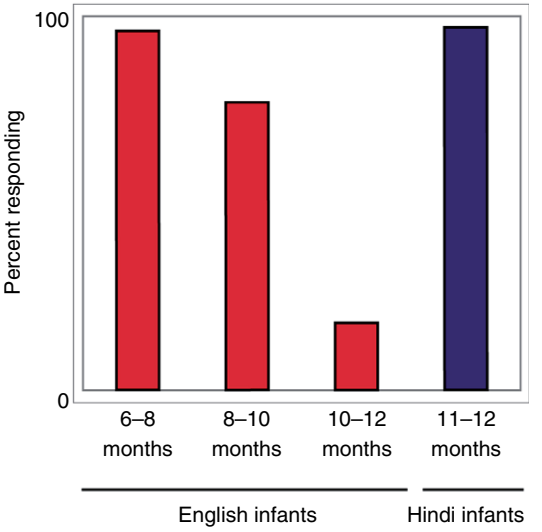

Figure 11 Perception of speech sounds is tuned by experience. As a consequence of experience with consonants in their native language, infants' tendency to respond to differences between some consonants that are not in their language begins to attenuate. Here, 6- to 8-month-old infants from English-speaking homes respond in a manner typical of native-Hindi adults and 1–12-month-old Hindi infants when hearing dental and retroflex Hindi stops. Before they are a year old, infants from English environments respond like native-English adults, treating both consonants the same. Adapted from Werker, J. F. and Lalonde, C. E., 1988 Cross-language speech perception: initial capabilities and developmental change. Dev. Psychol. 24, 672–683.

3.48.6.3 Second-Language Perception

The same principles that explain categorical perception and development of perceptual organization during the first year of life extend to predicting how difficult, or easy, it is to learn new speech contrasts in a second language. For the case of the sounds of a single language, correlated attributes distinguish each consonant or vowel from others in a fashion that optimizes sensitivity to differences. The same construct, habitual co-occurrence of acoustic attributes, constrains and predicts how listeners perceive familiar and unfamiliar sounds from a second language. There are three basic patterns of interaction between perceptual organization for the native language and the mapping of sounds from a second language.

First, acoustic attributes of two contrasting nonnative speech sounds can be equally well correlated with attributes corresponding to only a single native consonant or vowel. Consider the case for formant patterns contributing to categorization of stop consonants with varying place of articulation. For

example, both dental and retroflex stops such as those found in Hindi are acoustically realized in a manner quite similar to that for English alveolar stops. Given the range of ways English [d̪] is produced in the contexts of other speech sounds, there is ample overlap with acoustic attributes associated with both dental and retroflex stops. When [d̪] is produced in the environment of the retroflex continuant [r] as in drew, English [d̪] is shares multiple acoustic commonalities with the Hindi retroflex stop [ɖ]. Similarly, when English [d̪] is produced in the environment of a dental fricative such as [θ] in words like width, it is acoustically quite similar to the Hindi dental stop [d̪] (Polka, L., 1991). Given the facts about the distributions of acoustic attributes for alveolar stops in fluent English, attributes consistent with dental or retroflex stops are well correlated with attributes that co-occur in alveolar stops. Dental-like or retroflex-like acoustic attributes are accommodated within correlation structures for English alveolar stops via an increase in overall variance reflective of the observed variability in English alveolar stop production. Werker J. F. and Lalonde C. E.'s (1988) adult identification data are entirely consistent with this scenario. Stimuli that are identified by native-Hindi listeners as dental or retroflex are all assimilated into the set of stimuli identified as alveolar by native-English listeners. Best C. T. *et al.* (1988) referred to a similar process as single-category assimilation in her taxonomy of contrasts within an articulatory framework.

An analogous example of difficulty perceiving a distinction between two sounds is the well-known inability of native-Japanese listeners to detect the distinction between English [r] and [l] (e.g., Miyawaki, K. *et al.*, 1975). Japanese sounds include a consonant called a rhotic flap, and acoustic characteristics of these flaps overlap extensively with those of both English [r] and [l] (Sato, M. *et al.*, 2003). Consequently, acoustic attributes of [r] and [l] are equally well correlated with attributes corresponding to a single Japanese sound, and native-Japanese listeners are unable to hear, and consequently produce, the English distinction.

A related way non-native contrasts can be assimilated with native contrasts involves cases for which attributes of one sound from of a non-native contrast are very well correlated with attributes of a single native consonant or vowel, being effectively the same. Attributes of a second non-native sound fit less well with the correlation structure of the same native sound, but they do correspond better with that sound than with any other native sound. One example of this is the Farsi distinction between velar and uvular stops. Native-English listeners do not lose the ability to discriminate Farsi velars from uvulars. Instead, they perceive the Farsi voiced velar and uvular stops as being good and poor instances, respectively, of English /g/ (Polka, L., 1992). In this case, Farsi velar stops are perceived as good English velar stops because they share most or all of the acoustic/auditory attributes that comprise the correlated structure of English /g/. Farsi uvular stops share fewer attributes with those that co-occur for English [g]. Farsi uvulars somewhat, but not completely, fit the correlation structure of English [g]. A related process has been referred to as category-goodness assimilation by Best C. T. *et al.* (1988).

The third way native and non-native contrasts can interact can be found in cases where the native language does not exactly share a contrast with a non-native language, but the native language does have a similar contrast that facilitates perception of the non-native contrast. For example, French does not include a voicing distinction for dental fricatives such as /ð/-/θ/ (as in than and thank), yet native-French listeners can discriminate voiced from voiceless English fricatives by perceiving them as versions of French dental stops /d̪/ and /t̪/, respectively (Jamieson, D. G. and Morosan, D. E., 1986). Best C. T. *et al.* (1988) label this type of assimilation two-category because each sound of the non-native contrast maps more or less on to a different sound in the native language. Within the framework of correlated attributes, one would explain the fact that French listeners perceive the English fricatives as versions of French stops is because attributes of the dental fricatives are reasonably well correlated with attributes of the French dental stops as produced with typical allophonic variation in fluent speech.

This scenario leaves only those non-native distinctions that are roughly orthogonal to contrasts within the native language. Across the broad domain of possible mouth sounds, there always will remain some attributes that are not well correlated with any of attributes for any speech sounds within a given language. For example, attributes of the click sounds of Zulu are correlated with no sounds of English, and their perception should be, and is relatively unaltered by the process of learning English phonemes (Best, C. T. *et al.*, 1988). It should be noted that all of the patterns of performance above are consistent with Flege J. E.'s (1995) speech learning model (SLM) and with patterns of experience-dependent learning of speech contrasts (e.g., Flege, J. E. *et al.*, 1997; Imai, S.

et al., 2002). However, Flege's explanations of underlying processes that give rise to these patterns of performance are distinct at least in level of analysis, and he may or may not agree with specific aspects of the present authors' explanations.

3.48.7 To the Lexicon and Beyond

3.48.7.1 Lexical Development and the Emergence of Phonemes (or Something like Them)

In the introduction to this chapter, discussion of phonetic segments and phonemes as independent entities was decidedly circumspect. Throughout the foregoing, consonants and vowels have been described either as sounds or as correlations among acoustic attributes in the service of maximizing information transmission. They have not been described as inherently linguistic or as a discrete stage in processing. To borrow Angell's (Angell, J. R., 1907) dichotomy between functionalism and structuralism, discussion has been more about how and why, and less about the structuralist what of linguistic theory. Particular emphasis has been about how, and the focus now turns to why. The why of speech perception is to recognize words, and the end goal must be getting from the acoustic signal to words that have meaning. Within the information-theoretic perspective adopted here, one can construe the process of speech perception as one of successively reducing uncertainty sufficiently to arrive at words.

Over the years, some researchers have made a case that speech perception really is word perception without intermediate levels of analysis. There have been simulations of lexicons constructed directly from acoustic/auditory input *sans* phonemes (e.g., Klatt, D. H., 1980), and a number of investigators have argued for the primacy of holistic (word-size) organization in lexical development (e.g., Charles-Luce, J. and Luce, P. A., 1990; 1995; Jusczyk, P. W., 1986; Walley, A. C., 1993; Walley, A. C. *et al.*, 2003). For example, Charles-Luce and Luce (Charles-Luce, J. and Luce, P. A., 1990) argued that emergence of acoustic/auditory detail, such as consonants and vowels of words, within the lexicon is a consequence of – not antecedent to – learning more words. By such an account, as the number of words in the lexicon grows, increasing degrees of detail are required to sort each word from all the others.

Kluender K. R. and Lotto A. J. (1999), by contrast, suggested that neither words nor phonetic units may serve exclusively to structure the developing lexicon. Werker and Curtin (Werker, J. F. and Curtin, S., 2005), within their developmental framework for processing rich information from multidimensional interactive representation (PRIMIR), argue that infants have access to information for both phonetic units and the ways these units are grouped together into words. While PRIMIR is more of a framework than a detailed model, Werker and Curtin suggest that internal representations of phonemes become more firmly established and resistant to change as the lexicon grows.

The present emphasis of maximizing information transmission is consistent with concurrent development of statistical structures corresponding to consonants and vowels both preliminary to the lexicon and as an emergent property of lexical organization. In this chapter, speech perception has been described as a succession of processes operating upon the acoustic signal with varying levels of complexity. Common to all these processes is maximizing efficiency of information transmission by absorbing redundancies across inputs. For example, spectral contrast operates early, with trading relations and categorical perception operating later. Following these preliminary operations, one easily can imagine development of a nascent, but undetailed, lexicon of word forms. As a lexical space becomes increasingly populated, the covariance space becomes more complex. Predictable relationships among attributes, now with a phonetic segment-like grain, can be revealed resulting in a reduction in dimensionality of lexical items. The classic definition of phonemes is that they provide the minimal distinction between meaningful elements (morphemes) of language (Trubetzkoy, N. S., 1939/1969). Consequently, phonemes provide one of the most efficient ways to describe differences within the lexicon. Because phonemes provide efficient descriptors of lexical space, they emerge as dimensions of the developing lexical space by quite the same process that explains categorical perception, now operating over a larger time window.

One might suggest that positing phoneme-like dimensions as emergent properties of a lexical space obviates the need for anything resembling consonants and vowels preliminary to the lexicon. However, doing so violates principles of sensori-neural organization, these being that redundancies are extracted continuously with ascending levels of processing. Werker and Curtin's (Werker, J. F. and Curtin, S., 2005) proposal that phonemes become more established, and presumably increasingly tuned to

phonotactic regularities in a language, is more consistent with persistent successive absorption of redundancy in the service of maximizing sensitivity to change.

3.48.7.2 Finding Word Boundaries

One final example of auditory perception using predictability to enhance sensitivity to change is found in studies demonstrating how infants find boundaries between words. In connected speech, acoustic realization of the beginning and end of one word also overlaps with sounds of preceding and following words. Unlike white spaces between words on a page, there are no silent intervals that mark beginnings and ends of words. Interestingly, perception is at odds with this acoustic reality. When listening to someone talking, most individual words stand out quite clearly as discrete entities. But listening to someone speak in a different language is often a very different experience. Every phrase or sentence may sound like a single very long word. This is the situation faced by infants.

Saffran and colleagues (Saffran, J. R. *et al.*,1996) demonstrated that infants can use transitional probabilities between successive sounds within a speech stream as evidence for breaks between words. In their studies, they used streams of connected pseudowords, for which the probability of some sequences of consonant-vowels (CVs) was very high (1.0) while probability of other sequences was relatively low (0.33). Infants were sensitive to whether two sounds share a history of co-occurrence. When they heard successive CVs that rarely co-occurred with one another in their experience, they recognized this as a sign that there was a break between words. This discontinuity corresponds to a spike in information because one CV did not predict the occurrence of the next. Statistics of English support this emphasis upon word boundaries, as the ends of most words cannot be identified prior to the onset of the next (Luce, R. D., 1986). Infant sensitivity to boundaries is yet another example of using predictability to enhance sensitivity to change, and hence enhance transmission of information (Figure 12).

Because this is a principle of perceptual systems most broadly, one expects this use of predictability to apply most generally. Indeed, these patterns of performance extend to infants experiencing tonal sequences (Saffran, J. R. et *al.*, 1999), visual shapes (Kirkham N. Z. et *al.*, 2002), and visual-feature combinations (Fiser, J. and Aslin, R. N., 2002). In fact, even nonhuman primates (Hauser, M. D. *et al.*, 2001) exhibit this sensitivity to transitional probabilities.

3.48.8 Speech in the Brain

Given the plethora of relatively recent studies concerning speech processing using electroencephalography (EEG), magnetoencecphalography (MEG), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI), extensive depiction of speech processing in cerebral cortex alone requires one or more chapters. Here, a very brief review of current understanding will be placed within the framework of information processing provided above.

Hearing sounds of any kind activates primary auditory cortex (AI). Processing of complex sounds relies upon additional areas of cortex adjacent to AI, which is functionally divided into ventral, anterior,

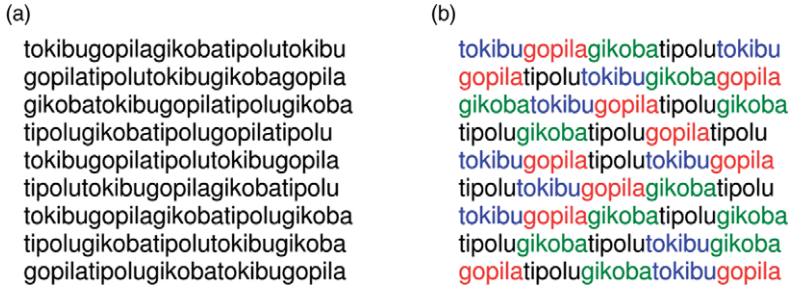

Figure 12 There are no acoustic markers between most words in a stream of fluent speech, analogous to the strings of letters on the right (a). Following minutes of experience with streams of connected speech in which probability of some sequences of consonant-vowels (CVs) is very high, while probability of other sequences was relatively low, infants are sensitive to whether two sounds share a history of co-occurrence. From Saffran, J. R. Aslin, R. N., and Newport, E. L. 1996. Statistical learning by 8-month-old infants. Science 274, 1926–1928.

and posterior sections. Neurons from AI project to the surrounding belt of cortex, and neurons from this belt synapse with neurons in the adjacent parabelt area. Just about any sound will cause activation in some part of AI. However, in the belt and parabelt areas, referred to as secondary or associational auditory areas, simple sounds such as sine waves and white noise elicit less activity, particularly if they have limited temporal structure. Thus, as in the visual system, processing proceeds from simpler to more complex stimuli farther along the auditory pathway, and there is also greater evidence of cross-modal processing (e.g., combining acoustic and optic information), particularly in parabelt areas. Of course, this general property of hierarchical organization is consistent with continuous and successive extraction of redundancy across increasing spans of space and time. As one might expect, areas beyond AI are activated when listeners hear speech and music. Further, at these early levels of cortical processing, activity in response to music, speech, and other complex sounds is relatively balanced across the two hemispheres.

When listening to speech, additional areas of both left and right superior temporal lobes along the superior temporal sulcus (STS) activate more strongly in response to speech than to nonspeech sounds such as tones and noise (e.g., Binder, J.R., 2000). While language processing is typically lateralized to one hemisphere, this activity in response to speech signals is relatively balanced across both sides of the brain when researchers have been very careful to avoid higher-level effects of language (Zatorre, R. J. and Binder, J., 2000).

At some point, however, processing of speech should become more lateralized as perceiving speech becomes part of understanding language. However, one challenge for researchers has been to create control stimuli that have all the complex properties of speech without being heard as speech. Because listeners are very good at understanding even severely distorted speech, it is very difficult to construct stimuli that are complex like speech without being heard as speech.

Liebenthal and colleagues (Liebenthal, E. *et al.*, 2005) adopted a creative way to control for acoustic complexity while varying whether sounds would be heard as speech. They synthesized speech syllables varying incrementally from [ba] to [da]. Nonspeech control stimuli were the same series of syllables, except characteristics of F_1 transitions were flipped upside down, decreasing in center frequency following syllable onset. It is impossible for a human vocal tract to create such sounds, and listeners could not identify them as consonants.

During scanning, listeners participated in a categorical perception task, discriminating pairs of stimuli from one or the other series of stimuli. For the [ba-da] speech series, performance was typical for categorical perception experiments, with stimuli that would be labeled differently (e.g., /ba/ vs. /da/) being almost perfect, while discrimination of other stimulus pairs was rather poor. For the nonspeech sounds, discrimination was above chance and pretty much the same for all pairs of stimuli. Listening to both series of stimuli resulted in increased activation in STS in both temporal lobes. When sounds were speech [ba-da] however, there was increased activation in STS superior temporal cortex, a bit anterior and ventral from activation for control stimuli and mostly in the left hemisphere. This research (Liebenthal, E. *et al.*, 2005) may have revealed a place in the left temporal lobe where experience with English [b] and [d] shapes neural activity.

This experience-dependent cortical organization for English consonants may have been predicted by previous work with visual processing of well-learned objects. In the visual system, perception of faces results in activation of the middle fusiform gyrus (or fusiform face area) of the cortex. This area is disproportionately activated when subjects view faces versus viewing other objects or scenes. Similar patterns of activation, in the same general brain region, can be found in response to other types of stimuli with which subjects are very familiar (Gauthier, I *et al.*, 1999).

A study by Scott and colleagues (Scott, S. K. *et al.*, 2000) suggest a cortical locus for the next step of processing of speech into language. They controlled for acoustic complexity while changing whether sentences were intelligible by using spectrally rotated sentences that could not be understood by listeners. Rotated speech signals were spectrographically upside down (i.e., the frequency scale was inverted). They could not be understood by listeners, but they were as complex acoustically as right-side-up sentences. Rotated stimuli activated STS comparably to intact nonrotated sentences, suggesting that auditory processing in these areas is related more to complexity than to being speech *per se.* The essential difference between cortical responses to these two types of stimuli was that, on the left temporal lobe, activation in response to intact sentences continued further anterior and ventral (including superior

temporal gyrus, STG) to the region activated by rotated sentences. Activation was a little anterior and ventral to the area in which Liebenthal and colleagues (Liebenthal, E. *et al.,* 2005) found activation for [b] and [d]. Relative left lateralization consequent to recognizability parallels findings for other environmental sounds (e.g., Lewis, J. W. *et al.*, 2004), albeit in different brain regions (Figure 13).

The extension of lateralized activation, increasingly anterior and ventral, discovered by Scott and her colleagues (Scott, S. K. *et al.,* 2000) inspires a tantalizing hypothesis concerning the next level of processing beyond speech perception to word recognition. Based upon neuropsychological data from patients, cortical areas essential to semantic memory may reside within far anterior temporal lobe (see, e.g., Rogers, T. T. *et al.*, 2004). Consider a scenario through which increasingly sophisticated redundancies are wrenched out of the speech signal, through differentiation of sounds such as [b] and [d], through detection of word boundaries, to regularities within word boundaries (i.e., words) and concomitant associations with semantic properties of words. Such a notion is clearly speculative given the present state of knowledge; however, this would be an elegant view of successive processing along increasingly anterior and ventral areas of temporal lobe.

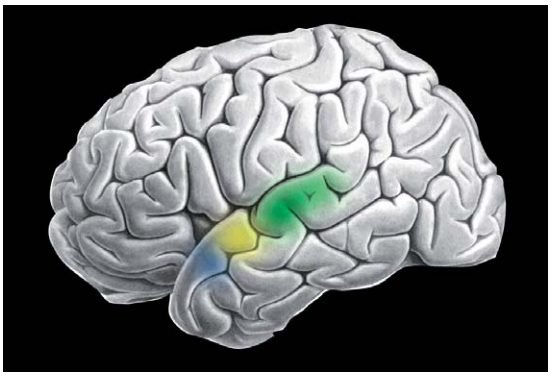

Figure 13 When listening to speech, as well as other complex sounds, cortical activity along the superior temporal sulcus (STS, green) is relatively balanced across the hemispheres. When acoustical complexity is carefully controlled, there is evidence of increased activation in STS (yellow), more anterior and mostly in the left hemisphere (Liebenthal, E. *et al.*, 2005). Cortical activation in response to recognizable sentences appears further anterior and ventral (blue), including superior temporal gyrus (STG). From Scott, S. K. Scott, S. K., Blank, C. C., Rosen, S., and Wise, R. J. S. 2000. Identification of a pathway for intelligible speech in the left temporal lobe. Brain 123, 2400–2406.

3.48.9 Conclusion

Speech perception is grounded in general principles that apply to other acoustic events and to other modalities. Classic principles that guide perception, none of which is wholly original to the authors, explain processes underlying multiple phenomena of speech perception. This information-theoretic model, operating from sensory transduction to word learning, is biologically realistic. It is intended that this framework will serve, not only to reveal processes underlying normative aspects of speech perception, but also to extend understanding of clinical conditions of speech and language processing. Finally, beyond being amenable to study like any other form of perception, speech perception holds promise as a fertile domain for research that can reveal and extend fundamental understanding of perception most generally.

Glossary

auditory scene analysis (ASA) Auditory scene analysis is the name for both a problem and a perceptual process. The problem is how to form mental representations of individual sounds from the summed waveform that reaches the ear of the listener. It is also the name of the brain process that accomplishes this result (with a greater or lesser degree of accuracy).

auditory stream A perceptual interpretation, produced by auditory scene analysis, of a mixed auditory input. Parts of the input are heard as separate coherent patterns evolving over time (auditory streams), and interpreted as individual acoustic sources present in the auditory environment (such as a voice, a violin, or a machine). More than one stream can be present at the same time. A stream (in ordinary conversation, we call it a sound or a sequence of sounds) is a perceptual entity, analogous to a visual object, capable of binding a cluster of properties (e.g., one sound is high in pitch, loud, and on the left, whereas the other sound is low in pitch, soft and intermittent, and straight ahead).

event-related potential (ERP) The electrical activity of the brain is measured on the scalp while external events (such as sounds) are presented to the subject. A large number of samples of the electrical recording that correspond temporally with some particular class of external event (such as an acoustic signal of a certain type) are extracted from the record of the brain activity and then aligned temporally using the start of the external event as a zero point, and averaged together. This averaging is thought to eliminate all other influences on the electrical wave except the occurrence of the event. This average wave is the ERP.

mismatch negativity (MMN) The MMN is a negative deflection in the human event-related potential recorded from frontal scalp electrodes, and is thought to originate in auditory cortex. It occurs when a change in a regularly repeating stimulus is detected by the brain, first a series of identical presentations of an auditory stimulus is presented. The repeating stimulus can be as simple as a single sound or as complex as a short pattern of sounds. Then, without a break, a change is introduced in the stimulus. The introduced change can be as simple as a single feature of the stimulus or as complex as an abstract relation between the stimuli of the repeating pattern. MMN is thought to represent the activity of an automatic process for

detecting change, since it occurs whether or not attention is directed toward the repeating stimuli.
objectrelated negativity (ORN) ORN is a component of ERPs that has a negative peak at around 150 ms relative to the onset of an acoustic signal. It occurs when the incoming spectrum is interpreted as two sounds rather than one, and is not sensitive to the involvement of attention.
stream segregation The formation of more than one auditory stream from a mixed input.
streaming A phenomenon in which a rapid sequence of tones or other acoustic units is interpreted as the co-occurrence of two or more auditory streams. The perceptual decomposition of the sequence of sounds into its component streams takes time to evolve.

3.49.1 The Problem of Mixtures

Most studies on perception, either by humans or other animals, have been done in very simplified setups, especially in the area of auditory perception. In a typical experiment in this area, listeners have been presented with an auditory signal in a background of silence, or perhaps noise, and required to judge (or, in the case of animals, to respond to) something about it: whether the signal is present, or whether it is different from a second signal in some quality such as loudness, pitch, or timbre. In the most complex case, speech signals, they may be asked to recognize the speech. This approach has given us what might be called the psychophysics of the isolated stimulus.

However, the acoustic signals we encounter in the natural world do not occur in isolation. The waves emanating from different events co-occur and overlap in time. A recording of a busy household might register a conversation, a child playing a game in an adjacent room, the clamor from a television set, and the mumble of an air conditioner, all overlapped in time. In the world of nonhuman animals in their natural environments, most of the signals are quieter than in a human household. However, these low-level signals are many: the wind, the flutter of birds' wings, insects buzzing, the chatter of small mammals, and the footsteps of larger ones. The symphony of the field is as complicated as that of the household, but with the volume turned down. In both cases, in order for listeners to recognize the signals individually, they must be able to undo the acoustic mixture. The brain process that accomplishes this has been labeled auditory scene analysis (ASA) (Bregman, A. S., 1984; 1990/1994). The critical importance of ASA can be understood by considering what would happen if the process made an error. Syllables from two different voices might be joined to make a single word. A cough in the audience might be heard as part of a piece of music. For a small animal, the noises made by the approach of a predator might simply contribute its qualities to the sound of a waterfall.

For clarity, in this discussion, we will use different terms to refer to the physical acoustic signals from those used for the mental structures and qualities to which they give rise. In the physical category, we will refer to acoustic sources and acoustic signals, or just signals, and, in the context of an experiment, stimuli. These will have properties or features, such as fundamental frequency, amplitude, spectral shape, etc. By an acoustic source, we mean any physical object or process that generates an acoustic signal by creating audible vibrations. By properties, or features, we mean physical properties (to be contrasted with perceptual qualities). Examples of acoustic sources include a person speaking, a violin playing, the wind howling, and a bird singing.

In the mental category, we will refer to sounds (not signals). These will have qualities (not properties), such as pitch, loudness, timbre, etc. So in our terminology, a signal has no pitch until the brain makes one or more sounds out of it, and assigns pitches to some of them. Timbre is a quality of a sound, not a property of a spectrum. Are these distinctions simply the product of an academic obsession with definitions? They seem to be so when we consider only the psychophysics of the isolated stimulus. However, they become essential when considering mixtures, where the qualities that emerge from the analysis depend on the particular parsing that the auditory system gives to the incoming spectrum, rather than on the way that experimenters describe the features of the physical signals that they have created. The perceived qualities of timbre, pitch, loudness, rhythm, etc., emerge from the way ASA allocates energy to individual auditory streams. A spectrum, in itself, does not

have a timbre, only a spectral composition; it may, for example, furnish the energy for two concurrent sounds, each of which has its own timbre.

Because the extracting of separate sounds usually goes on quite automatically in our own auditory systems, it is hard for us to realize how profound an accomplishment it really is. But consider the problem in physical terms. The time-varying acoustic pressure wave that reaches each of our ears is the arithmetic sum of the pressure waves emanating from the individual events that produced them. The individual events overlap in time, starting and stopping asynchronously, shaping the summed pressure wave. Yet what is needed for an appropriate response to the events around us is not a perceptual description of this happenstance mixture, but separate descriptions of the individual acoustic sources. Unfortunately, examining a short stretch of the waveform, or even its spectrum cannot tell us how the mixture was formed, since there are an enormous number of ways of decomposing it. The problem can only be solved by examining a longer window of time, analyzing the changes that occur over time, making use of some *a priori* constraints on the plausibility of particular decompositions.

3.49.1.1 How the ASA Problem Can Be Solved

We can see some of these constraints by looking at the spectrogram shown in Figure 1, of a mixture of the words, 'one, two, three', the sung syllables, 'da-da-da', a man whistling, and a computer fan. The spectrogram of the mixture is roughly what you would see if you made a spectrogram of each of these acoustic sources on separate pieces of clear plastic and superimposed them. In the audio recording from which this spectrogram was made, the individual signals are not hard for the ear to pick out.

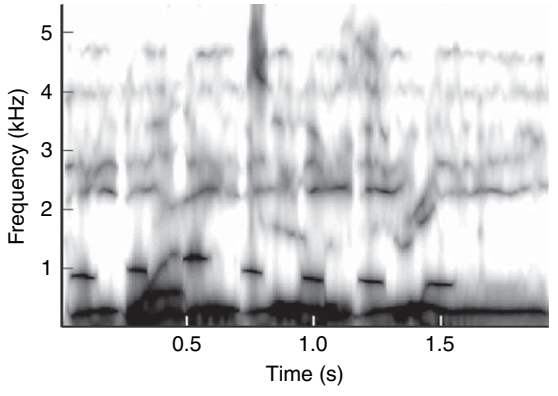

Figure 1 A spectrogram of a mixture, including the spoken words, 'one, two, three', a person singing 'da-da-da', a person whistling, and a computer fan. Adapted from Bregman, A. S. and Woszczyk, W. 2004. Controlling the Perceptual Organization of Sound: Guidelines Derived From Principles of ASA. In: Audio Anecdotes: Tools, Tips and Techniques for Digital Audio (*eds.* K. Greenebaum and R. Barzel), Vol.1, pp. 35–64. A K Peters.

The problem of using the summed spectrum to derive perceptions of the component sounds can be viewed as a problem in perceptual organization. Various parts of the energy present in this spectrum have to be allocated to form one percept and segregated from other groupings of energy that will be used to create other percepts. The difficulty is that the energy from the individual sound sources overlaps in frequency and time, and an individual frequency component may result from the summing of components from two sources. In Figure 1, we can see two dimensions of the problem, represented by the horizontal and vertical dimensions of the spectrogram.

In the horizontal dimension, listeners must group together the energy that came from the same acoustic source over time, a process called sequential organization (Bregman, A. S., 1990/1994, chapter 2). The organization across time does two things: (1) it forms each individual 'da' syllable from the moments of energy that compose it, giving it a beginning, a duration, and an end, thus making it into a temporal unit, and (2) it groups the individual 'da' syllables into a 'da-da-da' melody.

In the vertical dimension, the ASA process must allocate all the energy present at the same time to one or more concurrent sounds, each of which has emanated from a distinct acoustic source. This is called spectral organization or simultaneous organization (Bregman, A. S., 1990/1994, chapter 3).

3.49.1.1.1 The auditory stream

The mental representation of a distinct acoustic source, created by ASA, is called an auditory stream. Any acoustic input may yield a number of concurrent streams. Examples of streams include the mental representations of: (1) an individual voice, (2) a sequence of footsteps, (3) an approaching car, and so on. A stream in audition, like an object in vision, is a mental entity that is intended to correspond to an individual entity in the world, although its activities may unfold over time. Its role in perception is to act as a structure to which perceptual qualities can be bound. We say that a certain sound (the name we typically give to a stream) is loud, or nearby, or high in pitch, or voice-like, etc. There can be a number of

concurrent sounds (streams), each with its own qualities.

3.49.1.1.2 Regularities in acoustic mixtures

ASA takes advantage of regularities that cut across environments regardless of the provenance or meaning of the signal. For example, the various frequency components arising from an individual acoustic source (such as a voice or instrument) tend to start and stop at the same time. While not true without exception, this statistical regularity holds in deserts, jungles, households, in music, speech, and on Mars. The use of such general regularities by the auditory system is always useful. It is plausible that over evolutionary time, the auditory system has incorporated processes into its hard wiring that detect the general cues that signal the presence of an independent acoustic source within a mixture. These can be called primitive or built-in processes of ASA. One would expect them to be found even in young infants and in nonhuman animals.

However, the human listener is also capable of learning many regularities that apply in narrower environments. These probably include the phonetic components of one's own language and the articulations that give rise to them, the vocabulary of one's language, musical keys and scales, the sound qualities of various machines, the voice of one's own child, and so on. Humans operate in so many different environments that we possess a robust system for learning acoustic patterns, which can provide help in decomposing mixtures.

On the other hand, some nonhuman species, such as bats, operating in very specialized sonic environments and having a vital need to respond quickly to special types of acoustic signals, undoubtedly possess innate mechanisms in their perceptual systems that detect these signals even in mixtures, using the specific structure of these signals, rather than just the general regularities found in most acoustic mixtures.

3.49.1.2 Grouping of Acoustic Energy Based on Acoustic Regularities

Let us consider how the auditory system uses the general regularities to achieve sequential grouping. Going back to Figure 1, if we observe a sequence formed of spectral patterns that resemble one another, it is reasonable to assume that they may emanate from the same source. This assumption is based on the statistical regularity that most sounds change slowly if the proper timescale is chosen. The strategy derived from this regularity is: 'if patterns of spectral energy, not too far apart in time, resemble one another, they should be assigned to the same auditory stream'. This resemblance can be in terms of fundamental frequency, spectral center of gravity, spectral shape, intensity, temporal dynamics, spatial position, and perhaps other acoustic features.

Spectral or simultaneous organization also makes use of general regularities. Again we can use Figure 1 to understand them. We can see many examples in the spectrogram where energy at different frequencies starts and stops at the same time. This reflects the general fact that the components of a single sonic event tend to start and stop together. Accordingly, one of the principles used by ASA to organize simultaneous components is: 'if energy in different frequency regions or in different parts of space change in amplitude in the same direction at the same time, assign these to the same auditory stream'.

The justification for these principles and others like them derives from statistical regularities in our acoustic world. It is probable that successive wave patterns arising from the same source will resemble one another, though their properties may change slowly over time. This is not true without exception, but it is generally true, especially if you consider sufficiently short periods of time. This regularity justifies the principle of grouping a pair of signals A and B, which are close together in time and similar in properties into the same auditory stream and rejecting another dissimilar signal, C, that may occur between A and B into a different stream.

Here is another example. Many natural vibrations, including the human voice, animal calls, and insects flying, are harmonic. That is, they are formed of a fundamental frequency and many harmonics of that fundamental. The ASA system can use this as a constraint which favors the grouping of simultaneous components as parts of the same perceived sound if they appear to be harmonics of the same fundamental. Again, a regularity in the world becomes a constraint on the process of decomposing the acoustic input.

A final example has been called the old-plus-new heuristic (Bregman, A. S., 1990/1994, pp. 14, 222–227). It derives from the fact that unrelated signals rarely stop and start at the same time. Instead they overlap in time. As a signal starts, its spectrum is added to the ongoing spectrum resulting from already-present signals; so the spectrum becomes more complex and has a greater intensity.

This fact justifies the following rule in decomposing spectra: 'if a spectrum quickly changes so that it becomes more intense and more complex, do an analysis to determine whether the spectral components that were there just prior to the change are still present after the change. If they are, treat them as a continuation of the prechange spectrum and subtract them from the mixture. Treat whatever is left over as a new sound that has entered the mixture and ascertain its properties'. The moment of entry of the new sound into the mixture is an unparalleled opportunity to discover its properties since we can compare the spectrum just before and just after its entry.

3.49.1.2.1 Cooperation and competition in ASA

Despite the fact that these strategies capture important regularities in the world, and can serve as constraints in decomposing the mixture, each of them can be unreliable. For example: (1) occasionally the properties of the signal coming from a single acoustic source can change rapidly instead of slowly – think of yodeling; (2) the separate spatial origins of parts of the acoustic mixture can be unavailable if the signals are coming around a corner; or if we are listening to a monophonic broadcast or recording; and (3) the synchrony or asynchrony of onset of energy in different parts of the spectrum may be blurred in a highly reverberant environment. However, this unreliability can be dealt with by not depending too much on any individual regularity, but allowing them to collaborate and compete in determining the organization that emerges. If a process analogous to a voting system is used, so that the perceptual grouping is controlled by the greatest number of votes supplied by different strategies, the reliability of the system as a whole can be improved.

It is not just that different regularities (such as spatial proximity and fundamental frequency) compete with one another to control the parsing. Even the use of individual regularities such as separation in a frequency–time space may involve competition. Consider Figure 2. Tone B follows tone A at a certain distance in frequency and time. The question is whether A and B, as two tones in a four-tone repeating cycle, will be placed in the same stream or in different ones by ASA processes (Bregman, A. S., 1978). The answer depends on the properties of the other tones that are present. In the left panel, A and B are far from tones X and Y in frequency; so ASA isolates A and B in their own stream and X and Y in a second. The dashed lines show the resulting

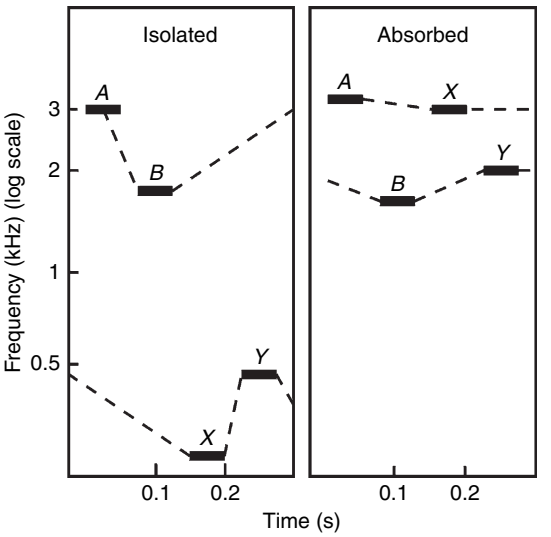

Figure 2 The stream membership of tones A and B, separated by a fixed frequency and time, depends on the context of other tones. The dashed lines show the streams that are formed. In the left panel, A and B are isolated in frequency from X and Y; so each set forms its own stream. In the right panel, X absorbs A into one stream and Y absorbs B into a second. Adapted from figure 2.27 in Bregman, A. S. 1990/1994. Auditory Scene Analysis: The Perceptual Organization of Sound. MIT Press (paperback 1994), with permission of MIT Press.

streams. The listener hears a repeating sequence AB – – AB– – ···, where the dashes represent the durations of X and Y, which appear as silences in the AB stream since they have been allocated to a stream of their own. In a lower frequency range, the listener hears – – XY – – XY···. The right panel shows how A and B can be absorbed into separate streams. Here X and Y are in the same frequency region as A and B, with X close to A, and Y close to B. Under these conditions, A and X form one stream, with the rhythm A – X – A – X ···, and B and Y form a second, with the rhythm – B – Y – B – Y···. The separation between A and B in frequency and in time are the same in the two panels. If there were a fixed separation that determined whether two sounds were assigned to the same stream, the grouping of A with B should be the same in both conditions. We can see, instead, that the frequency proximities compete, with the ASA system finding the tightest clusters that it can in the frequency–time space. Our ability to draw a picture that predicts the auditory grouping from the visual grouping encourages us to think that there are strong similarities between the grouping processes in vision and audition (Handel, S., 2006), many of which

seem to follow the principles set forth by the Gestalt psychologists (Koffka, K., 1935).

3.49.1.2.2 Validity of principles in the natural world

Simplified laboratory paradigms have been set up to study ASA. On the whole, involve the setting up of simplified stimulus patterns that can be perceived in two different ways depending on the perceptual organization, and then varying the features of parts of the stimulus pattern to see the effects on the perceived sounds. However, since the goal is to come to conclusions that are valid in the natural world, the relevance of the laboratory simplification has to be established by verifying whether the principles discovered in the laboratory are also found in the real world. To some extent this has been done by determining whether the discovered principles can be applied to music (Huron, D., 2001), to speech (Darwin, C. J., 1997, 2001), and to auditory displays (Shilling, R. and Shinn-Cunningham, B., 2002; see also Bregman, A. S., 1990/1994, chapters 5 and 6).

3.49.2 Sequential and Simultaneous Aspects of ASA

3.49.2.1 Sequential Organization

One paradigm for the experimental simplification of sequential organization is the phenomenon of stream segregation, sometimes called streaming (Bregman, A. S., 1990/1994, chapter 1) or fission (Van Noorden, L. P. A. S., 1975). Two tones of different frequencies (A and B) are played in a repeating cycle, either in the pattern ABABAB. . . , or the pattern ABA – ABA– · · · , where the gap between successive triplets is the same duration as the B tone. The latter is sometimes referred to as a galloping pattern because of its distinctive triplet rhythm. If the sequence is played rapidly, say 100 ms per tone, and if the frequencies of A and B are well separated, the sequence seems to split into two perceptual streams, a high one and a low one, each with its own timing pattern. In the case of the simple alternating ABAB. . . sequence, one hears an A stream, A – A – · · · , and a B stream, – B – B · · · , each with a rhythm at half the rate of the original integrated sequence. (Bregman, A.S., and Ahad, P. A., 1996; Van Noorden, L. P. A. S., 1975). In the case of the ABA – ABA– · · · pattern, the galloping rhythm disappears from perception and is replaced by two streams, one with the rhythm – A – A – · · · , and a slower one with the rhythm – – B – – B – – · · · In each case, the dashes represent the tone or tones lost to the other stream.

3.49.2.1.1 Main findings

The probability of segregation into two streams increases both with the time interval between the offset of one tone and the onset of the next tone of the same frequency, for example, the A-A interstimulus interval (Bregman, A. S. *et al.*, 2000) and with the frequency separation between the A's and the B's. One would think that these two facts would allow us to create a simple law relating seperation in frequency and time to stream segregation. However, segregation as a function of frequency and time is not the same for different patterns. For example, it is different for the two patterns described above, and may be different for different listeners (Van Noorden, L. P. A. S., 1975). However, the qualitative findings show that when acoustically different sounds occur in a rapid sequence, if some of the sounds are similar or identical, these will form their own stream.

The acoustic difference in the preceding example was in the frequency of pure tones. However, other differences have been shown in the laboratory to cause separate streams to emerge in rapid sequences of tones. These include differences in rise times, point of spatial origin, intensity, and the abruptness of transition between successive tones (smooth transitions favor integration of all tones into a single stream). Among complex tones, important differences include the repetition rates of their waveforms (perceived as pitch) and their spectral compositions (perceived as timbre). In sequences of bandlimited noise bursts, differences in their spectral centers on a logarithmic frequency scale (perceived as height) are important.

When substreams are created by the grouping of subsets of tones or noises, there are many effects on perception. For instance: (1) it is easier to detect the presence of a pattern of tones that is formed by the elements of one stream than one that crosses streams, (2) melodies and rhythms are formed within auditory streams, (3) judgments of timing are more precise when the time to be judged relates two sounds in the same stream then when the sounds are in different streams, (4) the continuity of synthetic speech is lost if you suddenly change the pitch of the voice, or (5) the perceived loudness of a signal can be reduced if part of its energy is interpreted by the old-plus-new heuristic as belonging to a previous sound (even if the signal is a pure tone).

3.49.2.2 Simultaneous Organization

3.49.2.2.1 The ABC paradigm

One of the simplest experimental paradigms for studying the grouping and segregation of simultaneous signals has been the ABC paradigm (Bregman, A. S. and Pinker 1978). The stimulus pattern is shown in Figure 3. We see a pure tone, A, followed by a pure tone, B, not far in frequency from A. Tone B is accompanied by another tone, C. The pattern is repeated over and over as a cycle. Its interpretation is ambiguous. B is sometimes heard as a second pure tone, grouping with A to form a sequential stream of pure tones, so that with the cyclic repetition, we hear A – B – A – · · ·. At the same time we hear a second stream, derived from C alone: – – – C – – – C· · ·. The arrows in the figure show the experimental variables. In different conditions, A may be closer or further from B in either frequency or time (Bregman, A.S. and Pinker, S., 1978; Rappold, P. W. *et al.*, 1993). As A gets closer to B, it is much more likely to capture it into an AB stream, leaving C in its own stream. The frequency and temporal position of C can also be changed in different conditions. The greater the asynchrony of onset or offset B of C, the more likely they will be allocated to separate streams. In the case of B, this means entering into an AB stream.

When B and C are both pure tones, the harmonic relation between them (e.g., whether B is exactly an octave away from C or not) has little effect. However, some experimental stimuli have been constructed in which C is not a pure tone like B but a tone with many harmonics. B and C may be aligned so that B serves as one of the harmonics in the complex tone C (that harmonic being otherwise missing from C's spectrum). If A and B are of the same frequency, B can be captured out of the C spectrum into an AB stream (Van Noorden, L. P. A. S., 1975, section 3.3). However, B is easier to capture when it is a little higher or lower in frequency than its ideal harmonic position (Hartmann, W. M., *et al.*, 1990). When it is a true harmonic of C, it seems to better able to resist the tendency to be captured by A into an AB stream. This illustrates the role played by harmonic relations in holding a set of spectral components together to form one coherent sound. Strangely enough, it is not only harmonic relations that integrate B with the components of C. Even if C is a nonharmonic set of components, but has a regularity in the spacing of its components (e.g., frequencies of 230, 430, 630, 830, . . . Hz), if B fits into this regular pattern, it seems to make it harder for it to be captured by A (Roberts, B. and Brunstrom, J. M., 1998; 2001). Why should ASA respond to this type of regularity? It is hard to think of a spectrum in nature whose components are not multiples of a common fundamental, but are nonetheless spaced regularly in some other way. The strongest possibility is that a regular, but unnatural, spectrum may trick a mechanism that has been evolved to integrate natural, harmonic components.

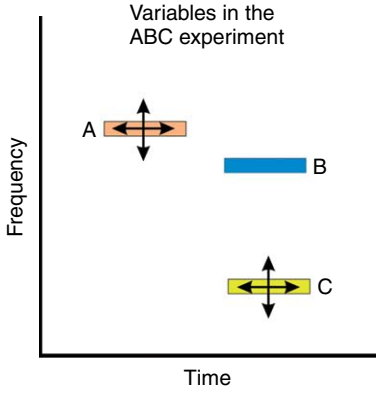

Figure 3 Stimuli for the ABC experiment. A, B, and C are pure tones. The pattern is repeated over and over as a cycle. The arrows show that both A and C may be varied in frequency or time. Adapted from figure 1.16 in Bregman, A. S. 1990/1994. Auditory Scene Analysis: The Perceptual Organization of Sound. MIT Press, (paperback 1994), with permission of MIT Press.

The ABC experiment shows that proximity in frequency and time tend to integrate a sequence of tones as parts of the same stream, just as they did in the galloping pattern of the stream segregation paradigm. It also shows that concurrent tones are better integrated into a single coherent sound when their onsets and offsets are synchronized., and when they fit into a set of frequency components that form a regular pattern in the frequency domain (the most important being the harmonic series).

3.49.2.2.2 Other findings

Other research has shown that simultaneous frequency components are somewhat more likely to be audible as separate sounds if they come from the different locations in space (Divenyi, P. L. and Oliver, S. K., 1989). This is, however, a weak effect when compared to those of asynchronous amplitude changes or the violation of harmonic relations.

Even in the integration of simultaneous components, the frequency separation of the components plays a role. This can be seen using narrow band noise bursts. The greater their frequency separation, the less likely they are to be integrated and heard as a single sound (Turgeon, M. *et al.*, 2002).

The perceptual effects of simultaneous organization are many. Whereas sequential integration forms auditory streams, the integration and segregation of simultaneous components determines which sounds are heard and their perceptual qualities. The number of sounds, their pitches, timbres, musical chord qualities, and even spatial locations depend on the organization of concurrent parts of the spectrum.

3.49.3 Brain Recording and the Role of Attention in ASA

There have been two major projects in the study of ASA using a biological approach. One has had the goal of clarifying the involvement of attention in ASA by recording the electrical activity of the brain that can be measured on the scalp. Is ASA, as claimed by (Bregman, A. S., 1990/1994) a preattentive process, or is attention involved? The advantage of brain recordings over purely behavioral testing is that it is easier to study the involvement of attention in ASA. The difficulty with trying to answer this question with behavioral research is that as soon as subjects have a task to perform with the acoustic material, they pay attention to it. With electrical recording, the subjects can be ignoring the acoustic input.

One approach has been to employ the mismatch negativity (MMN) component of auditory eventrelated potentials (ERPs) as a tool. After a series of repetitions of an unchanging short tonal pattern at a fixed rate, if some property of the pattern changes (e.g., the order of the tones in it) the ERP includes a negative component (the MMN), evoked by the detection of the change (Sussman, E. *et al.*, 1998; 1999). It is believed that this component reflects preattentive processing of the signal by the brain (Näätänen, R., 1992). MMN is found even if the subject's attention is engaged by a visual task (Näätänen, R., *et al.*, 2001). It has been possible to set up a paradigm in which the presence (or absence) of the MMN indicates that a sequence of tones has been segregated (or not segregated) into two or more auditory streams (Sussman, E. *et al.*, 1999; Sussman, E. S. *et al.*, 2005). Recent research on this topic has shown that when subjects are performing a difficult visual task and ignoring a sequence that has been made by interleaving three subsequences of tones, each occupying a distinct frequency range, three auditory streams can be formed concurrently. However, when the subjects are asked to focus their attention on one subsequence (e.g., the high tones), the MMN shows that the high-pitched stream is strengthened as a distinct perceptual entity, while the other two become weak or nonexistent (Sussman, E. *et al.*, 2005). There could be two possible explanations of this effect: (1) the ASA process requires auditory attentional resources that are being used to focus on one of the streams; therefore, it can only structure that particular stream; and (2) the absence of MMN is not due to the failure of the ASA system but rather of the MMN generating process: attention to one stream may suppress the MMN in the other streams. It is not yet clear whether either (or neither) of these explanations is correct.

A method has also been designed to use brain recordings to study the coherence of the sound resulting from multiple simultaneous components (Alain, C. *et al.*, 2001; 2002). Human subjects heard complex sounds composed of multiple harmonics, one of which could be mistuned so that it was no longer an integer multiple of the fundamental. With enough mistuning, the mistuned component stands out as a separate sound (Moore, B. C. J. *et al.*, 1986). In some conditions the subjects watched a silent movie at the same time to determine whether the mistuned component could be automatically detected. ERPs were recorded. Whenever a subject heard the mistuned component as a separate sound, a characteristic wave was obtained, first negative, peaking at about 150 ms after the onset of the sound, then positive, peaking at about 350 ms. The early negative wave, called object-related negativity (ORN) by Alain C. *et al.* (2001) was present both when the subjects were attending to the sound or watching the movie. The researchers interpreted the ORN as an index of a process that, without the involvement of attention, automatically decomposes the incoming signal into perceptual groups that can later be identified by higher processes in the brain.

These ERP studies are complemented by the work of Carlyon and his co-researchers, who studied the issue of whether ASA can go on without the involvement of attention, using behavioral tests on normal subjects and on patients with a unilateral attentional deficit (Carlyon, R. P. *et al.*, 2001). The research on normal subjects showed that the buildup of auditory streaming over time was greatly reduced or absent when they attended to a competing auditory task in the contralateral ear. Patients with an attentional neglect of the left side of space showed less stream segregation of tone sequences presented to their left than to their right ears. The researchers concluded that attention was needed for the

streaming phenomenon to occur. Presumably this research would lead one to suspect that ASA, in general, required attention.

Another question is whether attention is an indivisible mental process. The research by Sussman E. S. *et al.* (2005) cited above, suggests that auditory and visual tasks do not draw on the same pool of those particular resources that we label as attention. Performance in an engaging visual task permits three concurrent auditory streams to form; but attending to one of these streams (an exercise of auditory attention) may prevent the others from forming. Auditory attention itself may be divisible; even if ASA involves attentional resources, we still do not know whether unattended streams can be structured (perhaps by allocating a minority of attentional resources to them), in the circumstances of everyday life. It would be very useful to the animal if they could be. Then when attention was switched, it would be switched to a new partly organized auditory object, one for which an object node already existed in the nervous system, and not just to a smear of energy somewhere in the spectrum.

3.49.4 Animal Studies and Innate Processes of ASA

The study of nonhuman animals represents another approach to the biological study of ASA. If there are general regularities in the spectrum of a mixture that are present in all environments, and these regularities tell the listener how to parse it, one would expect that operations that used these regularities would be preprogrammed in the nervous systems of many species. However, one cannot assume that ASA works in the same way in all animals. For example, ASA has been studied in the echolocation of bats (e.g., Moss, C. F. and Surlykke, A., 2002). Some bats emit ultrasonic vocalizations containing frequency modulation (FM) at fairly stable rates (within 5%). They operate in a fairly complex environment in which both they and their prey are moving, and in which other bats are hunting too. Unlike humans, bats control the sounds they use for hunting; so that in order to segregate their own echoes from those of other bats, they can use strategies that go beyond the methods used by humans in ASA. It is argued that an individual bat adjusts the spectrum and sweep rate of its ultrasonic vocalizations so its own echoes will differ from those of its fellow hunters. Moss, C. F. and Surlykke, A. (2002) postulate that "the bat's perceptual system organizes acoustic information from a complex and dynamic environment into echo streams, allowing it to track spatially distributed auditory objects (sonar targets) as it flies." These streams serve the same function as those of humans – packaging a meaningful grouping of sounds (the reflections coming from a single prey animal) – but operate in an entirely different sonic environment. While the differences in how bats and humans achieve ASA is extreme because of bats' use of echolocation, even animals that do not use this method may live in acoustic worlds that are unlike the one humans inhabit. While the outcome of ASA has to be similar to that of humans, the particular cues and grouping principles may have to be different. Nevertheless, if we find a species whose ASA processes resemble those of humans, it should be possible to use physiological methods to investigate the brain structures and processes that humans may use.

3.49.5 Summary

This chapter describes some of the central issues in ASA. Considerable difficulty is involved in converting the incoming mixture of acoustic signals into separate mental representations of distinct sounds, each with its own properties. To parse the incoming spectrum, the human auditory system uses heuristic methods, based on general regularities in the world of acoustic mixtures. A set of such methods is used but no single one is decisive. They collaborate and compete to determine the final perceptual organization into distinct sounds and streams of sounds. There are two aspects of the ASA problem: how to group incoming energy over time, and how to do so over the set of components (or perhaps features) that are present concurrently. These two forms of grouping involve different regularities, but a competition for the simultaneous and successive grouping of a bit of spectral energy can occur until a final interpretation is resolved. Apart from the general regularities that are the basis for these methods, there are particular regularities in limited situations, such as in a particular language, or style of music, or type of machine, which may be learned and employed in addition to general regularities to parse the spectrum into separate overlapping auditory streams.

The role of attention in ASA is still in question and there have been some recent attempts to resolve this issue by means of brain recordings as well as behavioral studies. However, a decisive picture has

yet to emerge. Finally, it is hoped that the ASA concepts may clarify the perceptual activities of some nonhuman animals, and that having a good animal model of ASA may allow physiological explorations of the underlying processes in the central nervous system.

Glossary

auditory brainstem response (ABR) A scalp-recorded far-field evoked potential originating in the auditory nerve and auditory brainstem nuclei. Five peaks, labeled I through V, can be identified in the response. Wave I originates in the auditory nerve and has a latency of 1–2 ms in adults; wave V originates in the inferior colliculus and has a latency of about 7 ms in adults.

auditory filter width A psychophysical measure of frequency resolution obtained by measuring the threshold for a pure tone masked by a band-reject noise. The notch in the noise spectrum is centered on the tone frequency, and the width of the notch is varied to determine the width of the auditory filter.

binaural masking level difference (BMLD) The reduction in masking that occurs when either the probe or the masker is presented dichotically. For example, threshold for a tone is reduced by as much as 15 dB when the tone is presented in opposite phase to the two ears, while the noise masker is the same in both ears. The condition in which the same masker and probe are presented to both ears is denoted N_0S_0, while the condition in which the probe is out of phase at the two ears is denoted N_0S_π.

conductive apparatus The parts of the ear that conduct sound pressure to the inner ear; the external ear and the middle ear.

critical band The band of frequencies in a broadband noise that is effective in masking a tone; conceptually equivalent to the auditory filter width.

cross-modality loudness matching A method of measuring loudness in which the listener produces a stimulus in a nonauditory modality that matches the perceived magnitude of the sound. For example, the listener might draw a line that is as long as a sound is loud.

difference limen (DL) The threshold in a discrimination experiment; the difference between two

stimuli in intensity, frequency or some other characteristic that the listener can just discriminate.

formant transition Formants are peaks in the amplitude spectrum of speech sounds. As the articulators move from the position required to produce one sound (e.g., a consonant) to the position required to produce another (e.g., a vowel), the frequency of the formants gradually changes, creating a formant transition. The direction and extent of the formant transition provide information about the identity of speech sounds.

forward masking Masking that occurs when the masker precedes the probe by 0 to about 100 ms.

gap detection A measure of temporal resolution in which the listener is asked to detect a temporal interruption in a sound.

interaural time difference The difference between the arrival times of a sound at the two ears; a cue to sound source position in space.

minimum audible angle The just noticeable difference in spatial position of a sound source, expressed as degrees of arc.

observer-based method A method for determining thresholds in infants in which an observer, blind to trial type, judges whether or not a signal was presented to the infant in a defined time period. The only information provided to the observer is the infant's behavior. Because the method does not require a particular response from the infant, it is useful in the testing of young infants who do not produce easily recorded head turns to sound sources. The method is described in detail by Werner L. A. (1995).

otoacoustic emissions (OAE) Sounds that are produced by the inner ear and that can be recorded in the ear canal with a sensitive microphone. The presence of OAE is a sign of normal hearing.

psychometric function The function that describes the relationship between performance in a psychophysical task and the value of the stimulus. For example, the function that shows the percentage of correct detections as a function of stimulus intensity is the psychometric function for detection.

psychophysical tuning curve A measure of frequency resolution in which the masker level just required to detect a fixed-frequency probe is measured for different masker frequencies. A psychophysical tuning curve resembles the tuning curve of auditory nerve fibers.

release from masking A reduction in masking resulting from a change in the probe, the masker or some other variable.

sound source determination The process by which the components of sound emanating from a single source are grouped together as an auditory object.

visual reinforcement audiometry A clinical procedure for determining thresholds in infants older than 6–7 months. The infant learns to turn her head toward a sound source; a mechanical toy or video is activated to reinforce the infant's head turn.

3.50.1 Introduction

The study of auditory development in human infants and children is relatively young. Studies of anatomical (Streeter, G. L., 1906; 1917; McKinnis, M. E., 1936; Hall, J. G., 1964; Bredberg, G., 1968), physiological (Akiyama, Y. *et al.*, 1969; Engel, R. and Young, N. B., 1969; Lenard, H. G. *et al.*, 1969), and behavioral or psychophysiological (Bartoshuk, A. K., 1962; Steinschneider, A. *et al.*, 1966; Clifton, R. K. *et al.*, 1968; Jordan, R. E. and Eagles, E. L., 1963; Eisenberg, R. B. *et al.*, 1964; Leventhal, A. and Lipsitt, L. P., 1964) development had been published prior to 1970. It was, however, only in the 1970s that interest in assessing hearing in infants became serious, with the appearance of visual reinforcement audiometry (Moore, J. M. *et al.*, 1977; Liden, G. and Kankkonen, A., 1961) and the auditory brainstem response (Salamy, A. *et al.*, 1975). The first rigorous psychophysical studies of infants and children were published in 1979 (Schneider, B. A. *et al.*, 1979), and it is only in the last 15 years that attempts have been made to relate age-related changes in auditory behavior to the underlying physiological and anatomical processes (e.g., Ponton, C. W. *et al.*, 1996; Trainor, L. J. *et al.*, 2001; Werner, L. A., 1996; 1994b). The upshot is that while we have a fairly complete description of the development of the most basic aspects of audition, less is known about complex auditory perception and about the underlying causes of auditory development.

It is generally believed that the limits on the basic aspects of audition – frequency, intensity, and temporal resolution – are established at the auditory periphery. Deficits in resolution in mature listeners generally result from peripheral damage or disease. Observations of the human fetal and neonatal inner ear indicate that the cochlea is structurally and functionally adult-like by term birth (e.g., Bredberg, G., 1968; Lavigne-Rebillard, M. and Pujol, R., 1987; Lavigne-Rebillard, M. and Bagger-Sjoback, D., 1992; Pujol, R. and Lavigne-Rebillard, M., 1992; Lasky, R. *et al.*, 1992; Brown, A. M. *et al.*, 1994; Bargones, J. Y. and Burns, E. M., 1988; Abdala, C., 1996). These observations have led to the expectation that the basic aspects of hearing will likewise be adult-like at term birth, with any apparent immaturity in auditory behavior resulting from limitations in cognition or motor processes. However, just as we now understand that some types of purely auditory dysfunction can result from deficits in the neural encoding of sound (e.g., Zeng, F. *et al.*, 2005), we understand that immaturity of the primary auditory neural pathway may lead to immaturity of frequency, intensity, or temporal resolution. Further, we must recognize that maturation of fundamentally auditory processes, such as sound source determination, may limit basic auditory sensitivities. Finally, immaturity of the so-called higher-level processes, such as attention or memory, may result in immaturity of auditory sensitivity that is functionally no different from that resulting from primary auditory immaturity. Thus, potential contributors to the development of auditory behavior include primary auditory processes at both peripheral and central levels, organizational and integrative auditory processes, and general perceptual, cognitive and motor processes.

In many ways, the methods available to describe and to understand human auditory development are limited. Few anatomical data are available and physiological indices are limited to acoustic measures, scalp-recorded far-field potentials, and recently neural imaging techniques. In addition, infants and children have limited capacities for carrying out psychophysical procedures. However, some 30 years of work honing developmental psychoacoustic procedures has resulted in what we believe to be valid and reliable measures of auditory sensitivity. The details of these procedures are beyond the scope of this chapter. The interested reader is referred to Werner L. A. and Rubel E. W. (1992).

3.50.2 Development of Primary Auditory Capacities

3.50.2.1 Spectral Coding

3.50.2.1.1 Frequency resolution and discrimination

Schneider B. A. *et al.* (1989) published the first comprehensive description of masked thresholds from infancy through adulthood. The beauty of this study is that very similar methods were used to obtain data from listeners in all age groups, 6 months to 20 years. Listeners in this study detected octave bands of noise masked by a broadband noise by identifying the speaker – left or right – that was playing the octave-band signal on each trial. Infants indicated their choice with a head turn toward the correct speaker. Older listeners pushed a button on one of the arms of their chair. This two-alternative forced-choice method also has the advantage of controlling response bias. Thresholds were estimated from psychometric functions constructed from the data of all listeners in each group. The thresholds Schneider B. A. *et al.* obtained are plotted in Figure 1 for several frequencies. Notice that masked thresholds improve with age at all frequencies. Between 6 months and adulthood the improvement is on the order of 10-12 dB, with all but a few dB of the improvement occurring prior to 8 years of age. This pattern of development was confirmed in many studies of infants or children (e.g., Bargones, J. Y. *et al.*, 1995; Berg, K. M., 1993; Berg, K. M. and Boswell, A. E., 1999; Maxon, A. B. and Hochberg, I., 1982; Nozza, R. J. and Wilson, W. R., 1984).

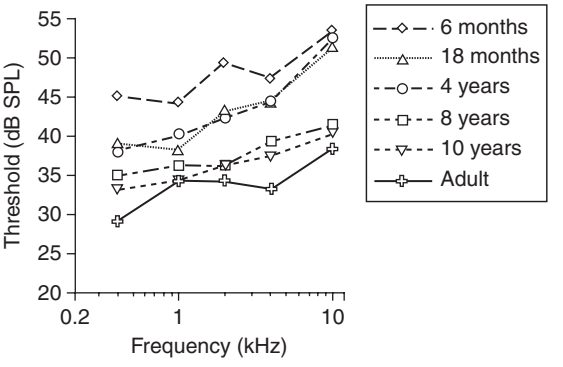

Figure 1 Thresholds for octave bands of noise masked by broadband noise, as a function of the center frequency of the noise band, for six age groups. Reproduced from Schneider, B. A., Trehub, S. E., Morrongiello, B. A., and Thorpe, L. A. 1989. Developmental changes in masked thresholds. J. Acoust. Soc. Am. 86, 1733–1742, with permission.

The observations by Schneider B. A. *et al.* (1989) provided the starting point for much of the developmental psychoacoustic research that followed. The age-related improvement in masked threshold could result from maturation of several different processes. Of course, the most obvious explanation for threshold maturation to most people is that people get better at performing psychophysical tasks as they develop. For example, listeners are better able to remain on-task and to remember what they are listening for. The consensus is that while inattentiveness or forgetting are likely responsible for young listeners' imperfect psychoacoustic performance, such processes can only account for 2–3 dB of the observed age difference in masked threshold (discussed in greater detail in Section 3.50.3; see also Schneider, B. A. and Trehub, S. E., 1992; Viemeister, N. F. and Schlauch, R. S., 1992; Werner, L. A. and Bargones, J. Y., 1992; Wightman, F. and Allen, P., 1992).

Another obvious process affecting detection in noise is frequency resolution, the precision with which the auditory system can analyze the frequency content of a complex sound. Frequency resolution improves dramatically in the period following the onset of cochlear function in mammals, and there is evidence that some neural responses continue to become more frequency selective even after cochlear tuning is well established (Sanes, D. H. and Walsh, E. J., 1998). In humans, the cochlea begins to function in the prenatal period, probably around 22 weeks of gestation (Pujol, R. *et al.*, 1990;1991). Both behavioral and brainstem evoked potentials can be recorded around 28 weeks of gestation (e.g., Birnholz, J. C. and Benacerraf, B. R., 1983; Lary, S. *et al.*, 1985). By term birth, acoustic and electrophysiological measures of cochlear function are generally reported to be adult-like (Teas, D. C. *et al.*, 1982; Abdala, C. and Chatterjee, M., 2003), save for the potential effects of conductive immaturity (discussed further ahead). Frequency resolution has been examined at the level of the brainstem using the auditory brainstem response (ABR) and masking paradigms by Folsom and his colleagues (Folsom, R. C., 1985; Folsom, R. C. and Wynne, M. K., 1987; Abdala, C. and Folsom, R. C., 1995). Their results consistently indicate mature frequency resolution at 6 months postnatal age. At 3 months, however, they report immaturity of frequency tuning, but only at frequencies above 4000 Hz.

The results of psychoacoustic studies of the development of frequency resolution are consistent with ABR results. For example, critical bandwidth (Schneider, B. A. *et al.*, 1990) and psychophysical tuning curve width (Olsho, L. W., 1985) have been reported to be adult-like in 6-month-old listeners. Spetner N. B. and Olsho L. W. (1990) conducted the only psychophysical examination of frequency resolution in infants younger than 6 months of age. These investigators reported that psychophysical tuning curve width was mature by 3 months of age at 500 and 1000 Hz, but remained immature at 4000 Hz. They also found that tuning was mature at 4000 Hz by 6 months. Several studies have examined frequency resolution in older children. While initial results indicated immature frequency resolution in 3- to 4-year-olds (Allen, P. *et al.*, 1989; Irwin, R. J. *et al.*, 1986), Hall J. W. and Grose J. H. (1991) showed that the apparent immaturity in frequency resolution in young children could be accounted for by age-related changes in perceptual decision processes. Thus, there is now general agreement that frequency resolution matures relatively early in postnatal life, and that age-related differences in masked threshold must stem from other causes. The nature of these other causes is discussed in detail in the following.

One would expect that the development of frequency discrimination would follow that of frequency resolution. The available data suggest that, in fact, high-frequency pure-tone discrimination develops along a course similar to that of frequency resolution at high frequencies: 3-month-old infants are immature in frequency discrimination from 500 to 4000 Hz, while 6- and 12-month-old infants remain immature at 500 and 1000 Hz but are close to adult-like at 4000 Hz (Olsho, L. W. *et al.*, 1987). Studies of children support this pattern of development, showing low-frequency pure-tone discrimination only reaching adult levels of performance around 10–11 years (Fischer, B. and Hartnegg, K., 2004; Maxon, A. B. and Hochberg, I., 1982). One explanation for this developmental gradient begins with the observation that low-frequency tones are discriminated on the basis of periodicity, while high-frequency tones are discriminated on the basis of excitation pattern (e.g., Moore, B. C. *et al.*, 1999). Frequency resolution and high-frequency discrimination are mature by around 6 months of age, as noted above. Immature low-frequency discrimination is consistent with immaturity of periodicity processing, either the primary representation of periodicity (i.e., phase-locking) or the ability to use that representation in the case of pure-tone frequency discrimination. Several lines of evidence point toward the latter possibility. First, the development

of evoked potentials, at least at the brainstem level (e.g., ABR), is generally complete before a child is 5 or 6 years old (Hall, J. W. III., 1992). Because evoked potential amplitude depends heavily on the existence of phase locking, this finding implies that phase locking is also mature by that age. Further, it is generally believed that more training is required to learn low-frequency discrimination, even among adults, and several studies support this belief (Olsho, L. W. *et al.*, 1988a; Harris, J. D., 1952). Soderquist D. R. and Moore M. (1970) have shown that young children can achieve adult levels of performance in low-frequency discrimination with training. Thus it appears that the periodicity information may be available even to infants, but that in the context of pure-tone frequency discrimination, listeners do not readily access that information.

3.50.2.1.2 Pitch and timbre

Complex pitch perception requires not only an adequate representation of the spectrum and periodicity of the stimulus, but some integration of temporal and spectral information across frequency regions, making it an interesting phenomenon from a developmental standpoint. Clarkson M. G. and her colleagues have conducted a series of studies examining the perception of complex pitch in 7-month-old infants. The phenomenon that defines complex pitch psychophysically is the pitch of the missing fundamental: people will assign a harmonic complex the pitch associated with its fundamental frequency, even when the fundamental frequency is not part of the complex. The perception of the pitch of the missing fundamental clearly depends on integration of the information carried by the harmonics, and Clarkson M. G. and Clifton R. K. (1985) first demonstrated that infants can learn to respond when the missing fundamental frequency of a complex changes, while ignoring other spectral changes. In many respects, infants' and adults' ability to perform this task depends on the same stimulus parameters. For example, both infants and adults continue to hear the pitch of the missing fundamental when a noise band masks the fundamental frequency, but fail to hear that pitch if the higher-frequency harmonics are masked (Montgomery, C. R. and Clarkson, M. G., 1997). Both age groups have greater difficulty categorizing the pitch of inharmonic complexes (Clarkson, M. G. and Clifton, R. K., 1995), but while adults can hear the pitch of the missing fundamental, albeit weakly, when only high-frequency harmonics are present, infants appear unable to hear this less salient pitch (Clarkson, M. G. and Rogers, E. C., 1995). Because the perception of the pitch of the missing fundamental on the basis of only high-frequency harmonics is believed to depend on the periodicity that results from unresolved harmonics, the latter observation provides additional evidence that infants may have greater problems in tasks that require the use of periodicity.

Finally, infants' ability to categorize spectrally dissimilar sounds on the basis of their common fundamental frequency would mean little if infants are unable to discriminate the spectral dissimilarity. Adults perceive these spectral changes as changes in timbre. One of the difficulties in ensuring that the listener is responding on the basis of the timbre of a complex is that the listener could listen to only a restricted frequency region of the complex and respond when the energy in that frequency region changes, regardless of the spectral shape of the complex as a whole. To prevent that from happening, studies of timbre generally vary, or rove, the overall intensity of the complex from presentation to presentation, so that the amount of energy in any frequency region is not a reliable indicator of a change in spectral shape. Several studies have reported that infants can learn to categorize sounds on the basis of spectral shape (Clarkson, M. G. *et al.*, 1988; Clarkson, M. G., 1996; Trehub, S. E. *et al.*, 1990), but infants have difficulty ignoring random changes in overall intensity (Clarkson, M. G., 1996). None of the existing studies has been able to get infants to respond to timbre changes in tonal complexes when the intensity is roved sufficiently to prevent the listener from responding on the basis of local intensity changes. Because infants are consistently able to discriminate between sounds that adults distinguish on the basis of spectral shape (e.g., vowels, Marean, G. C. *et al.*, 1992; Kuhl, P. K. and Miller, J. L., 1982) and because infants appear to have difficulty listening to a restricted frequency region (discussed in the following, Bargones, J. Y. and Werner, L. A., 1994), it is likely that they do perceive timbre in some fashion. However, a definitive demonstration remains elusive.

3.50.2.2 Intensity Coding

A difficulty in studying the development of intensity processing is that it is difficult to separate the perception of intensity from other variables that influence the efficiency with which the listener performs the task. There is no measure, like critical bandwidth or

auditory filter width that allows intensity coding to be distinguished from factors like attentiveness or memory. To date, the most fruitful approach has been to examine the effects of stimulus variables (e.g., frequency, duration) on intensity processing: the more adult-like these effects, the more likely it is that intensity processing is adult-like. A goal of future developmental research in this area, however, should be to find more definitive procedures for solving this dilemma.

3.50.2.2.1 Absolute sensitivity

To many, and certainly to audiologists, absolute sensitivity represents the most basic characterization of the auditory system. Threshold sensitivity improves dramatically in the period following the onset of cochlear function in the species that have been tested (e.g., Ehret, G., 1976; Zimmermann, E., 1993; Ehret, G. and Romand, R., 1981; Gray, L. and Rubel, E. W., 1985; Kenyon, T. N., 1996), but to date, no species has been followed systematically from the onset of hearing to adulthood in a single study. Because different methods are generally used to test the behavioral thresholds of young and adult animals, it is difficult to know how much of an age difference in threshold is due to differences in test methodology. In no case have thresholds of the oldest developing animal been found to approach adult thresholds in that species. The usual conclusion drawn from these studies, nonetheless, is that the development of threshold sensitivity is primarily due to maturation of the inner ear, although middle-ear function is also known to undergo developmental improvements early in life (e.g., Ehret, G., 1976). Neural contributions to threshold development are rarely if ever considered.

The human fetus moves in response to sound by 28 weeks of gestation. While a few attempts to measure behavioral response thresholds *in utero* have been made (reviewed by Lecanuet, J. P., 1996), the technical difficulties involved in estimating the sound pressure level *in utero*, not to mention the myriad other methodological difficulties involved in this experiment, make interpretation of the results problematic. Moreover, it is clear that whatever sound makes it to the fetus is at least partially masked by noise produced by the mother's body (e.g., Querleu, D. *et al.*, 1988; Gerhardt, K. J. *et al.*, 1990). A few studies have examined the behavioral response of preterm infants to sound. The percentage of behavioral responses to a broadband noise centered at 3000 Hz with a peak intensity of 90 dB SPL A has been reported to increase more or less systematically from about 20% to about 45% of trials between 34 and 41 weeks conceptional age (Gerber, S. E., 1985; Mencher, G. T. *et al.*, 1985), but it is, of course, difficult to know what is responsible for the increase in responsiveness to sound. If spontaneous responses to octave-band noises are considered, even in a rigorous psychophysical procedure, behavioral response thresholds in full-term newborns are on the order of 75 dB HL over the frequency range from 125 to 4000 Hz (Weir, C., 1976; 1979).

By 1 month of age, human infants are awake and alert long enough that a few attempts have been made to establish their behavioral thresholds using the observer-based approach. For example, Werner L. A. and Gillenwater J. M. (1990) estimated that 2- to 4-week-old infants' behavioral thresholds to pure tones were about 45 dB higher than adults' at 500 Hz and about 35 dB higher than adults' at 4000 Hz. Trehub S. E. *et al.* (1991) found that thresholds for a 4000 Hz octave-band noise were about 30 dB higher in 1-month-olds than in adults, and Tharpe A. M. and Ashmead D. H. (2001) reported that infants between 0 and 3 months of age had thresholds for a speech filtered noise that were about 40 dB higher than adults'. None of these studies reinforced the infants' responses to sound; Werner L. A. and Mancl L. R. (1993) reported that 1-month-olds' thresholds for pure tones were improved by about 5 dB if responses to the tones were reinforced by an audio recording of a woman reading from a children's book.

By 3 months of age, infants' behavioral thresholds improve to about 40 dB SPL at 500 Hz and to 24 dB SPL at 4000 Hz (Olsho, L. W. *et al.*, 1988b; Tharpe, A. M. and Ashmead, D. H., 2001; Trehub, S. E. *et al.*, 1991). Between 3 and 6 months, little improvement occurs in low-frequency thresholds, but thresholds are about 15 dB higher than adults' at higher frequencies (Bargones, J. Y. *et al.*, 1995; Berg, K. M. and Smith, M. C., 1983; Nozza, R. J. and Wilson, W. R., 1984; Sinnott, J. M. *et al.*, 1983; Trehub, S. E. *et al.*, 1980). Trehub S. E. *et al.* followed the development of thresholds for octave noise bands from 6 months through the school years to adulthood. They found that mature sensitivity was achieved earlier at higher frequencies, before age 5 years at 4000 and 10000 Hz, but after 10 years of age at 1000 Hz. Thus, the development of absolute sensitivity is a prolonged process, summarized in Figure 2.

The nature of these age-related changes in sensitivity have been a matter of debate. Certainly similar

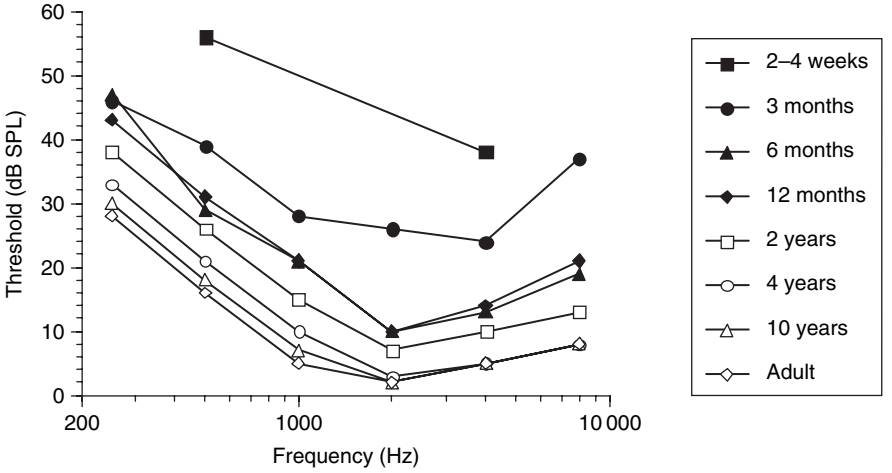

Figure 2 A summary of the development of the audibility curve, abstracted from several studies (see text).

improvements in physiological indices of sensitivity are observed in preterm and young infants. Improvements in click-evoked auditory brainstem thresholds from 40 to 10 dB nHL have been documented from about 28 to 38 weeks conceptional age on (Lary, S. *et al.*, 1985). In general, thresholds for responses generated in the inner ear or auditory nerve at term birth have been reported to be no more than 15 dB higher than those observed in adults (Engel, R. and Young, N. B., 1969; Stuart, A. *et al.*, 1993; Stevens, J. C. *et al.*, 1990; Abdala, C. *et al.*, 2006). Sininger and her colleagues (Sininger, Y. and Abdala, C., 1996; Sininger, Y. S. *et al.*, 1997) have reported that for stimuli calibrated in the ear canal, thresholds for click-evoked ABR wave V are about 20 dB higher in term neonates than in adults. This laboratory also reported that while neonates' thresholds for tone-pip-evoked ABR wave V are adult-like at 500 Hz, they are about 20 dB higher than adults' at 4000 and 8000 Hz.

One of the factors known to contribute to the improvements in absolute sensitivity with age is maturation of the conductive apparatus. Keefe D. H. and his colleagues (Keefe, D. H. *et al.*, 1993; Keefe, D. H. and Levi, E. C., 1996) have shown that the efficiency of transmission through the middle ear improves throughout infancy, and it is believed that this process continues well into childhood (Okabe, K. S. *et al.*, 1988). In 1-month-olds, as much as 20 dB less sound energy is transmitted through the middle ear at high frequencies, compared to adults. At lower frequencies, the difference in sound transmission is only 5–10 dB at 1 month. Transmission at high frequencies improves by 10 dB by 6 months of age; low-frequency transmission improves at a slower rate. Thus, it is likely that age-related threshold differences in otoacoustic emissions (OAE), ABR, and other measures of peripheral function early in infancy can be accounted for by immaturity of the conductive apparatus. Further, improvement in conductive efficiency can account for at least a portion of the improvement in behavioral thresholds observed between 1 month and 6 months of age, especially at higher frequencies. In fact, Werner L. A. and Holmer N. M. (2002) have shown that behavioral threshold at 4000 Hz is significantly correlated with middle ear admittance at that frequency among 3-month-old infants and among adults.

One of the factors unlikely to contribute to improvements in absolute sensitivity with age, at least beyond the conceptional age of 38 weeks or so, is maturation of the inner ear. On the basis of anatomical benchmarks, as well as physiological and behavioral responses, the human inner ear apparently begins to respond to sound around 22 weeks gestational age (Birnholz, J. C. and Benacerraf, B. R., 1983; Pujol, R. *et al.*, 1991). By term birth, the consensus is that the cochlea is anatomically and functionally mature (Fujimoto, S. *et al.*, 1981; Igarashi, Y. and Ishii, T., 1979a; 1979b; Igarashi, Y. *et al.*, 1978; Lavigne-Rebillard, M. and Pujol, R., 1987; 1988; 1990; Lavigne-Rebillard, M. and Bagger-Sjoback, D.; 1992, Bredberg, G., 1968; Igarashi, Y. and Ishii, T., 1980; Streeter, G. L., 1917; 1906; Lavigne-Rebillard, M. and Pujol, R., 1990; Isaacson, G. *et al.*, 1986; Shimizu, T. *et al.*, 1991; Hoshino, T., 1990; Nakai, Y., 1970; Bargones, J. Y. and Burns, E. M., 1988; Leiberman, A. *et al.*, 1973; Plinkert, P. K. *et al.*,

1990; Abdala, C., 1998; Chuang, S. W. *et al.*, 1993; Morlet, T. *et al.*, 1996; Eggermont, J. J. *et al.*, 1996; Collet, L. *et al.*, 1993).

Maturation of the primary auditory neural pathways, however, may well be involved in threshold improvements during early infancy. Werner L. A. and her colleagues (Werner, L. A. *et al.*, 1993; 1994b) have shown that behavioral threshold at 4000 and at 8000 Hz is significantly correlated with ABR threshold in the same infants, but even more strongly correlated with wave I–V interpeak latency. Improvement in ABR latencies during infancy is thought to result from changes in the length of the neural pathway, from myelination of nerve fibers, and in great part, from improvement in synaptic efficiency (Ponton, C. W. *et al.*, 1996; Moore, J. K. *et al.*, 1995; 1996; 1997; Ponton, C. W. *et al.*, 2000). It is likely that the improvement in synaptic efficiency, at least, also leads to improvements in auditory sensitivity.

3.50.2.2.2 *Intensity discrimination*

A notable property of immature auditory neurons is their limited dynamic range (Kotak, V. and Sanes, D., 1995). Thus, it would not be surprising to find that intensity discrimination undergoes postnatal development in humans. Because detection in noise is immature in infants and young children and because frequency resolution is apparently mature early in infancy, the development of masked thresholds must reflect changes in the signal-to-noise ratio required for detection. We refer to the signal-to-noise ratio required for detection as efficiency. One of the variables that determines efficiency is intensity resolution. Of course, many other factors, such as attentiveness, selective attention, motivation, and memory, also determine efficiency. Nonetheless, one would predict that the ability to detect changes in the intensity of a suprathreshold sound follows a developmental course similar to that for masked thresholds.

A summary of the development of intensity discrimination taken from several studies of infants and children is shown in Figure 3. In general, intensity discrimination has been found to be relatively immature in infants. For pure tone intensity discrimination, 6- to 9-month-old infants have been reported to have intensity difference limens (DL) on the order of 6–9 dB, compared to a DL of 1–2 dB in adults (Sinnott, J. M. and Aslin, R. N., 1985; Berg, K. M. and Boswell, A. E., 1998; Kopyar, B. A., 1997). Infants are more adult-like in intensity

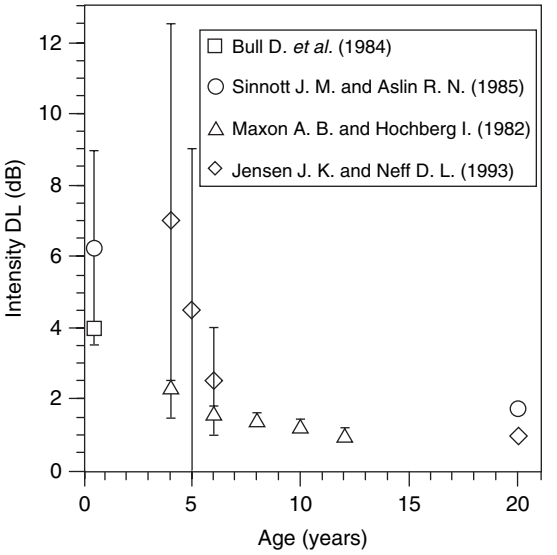

Figure 3 A summary of the development of intensity discrimination, taken from four different studies. Error bars represent ± one standard deviation. Stimuli varied across studies (see text).

discrimination of broadband than narrow band sounds (Bull, D. *et al.*, 1984; Kopyar, B. A., 1997). Although there is considerable variability in the intensity DL reported for children in different studies, there is a general trend for intensity discrimination to improve through the preschool period and to approach adult levels at 5–6 years of age (Jensen, J. K. and Neff, D. L., 1993; Maxon, A. B. and Hochberg, I., 1982; Berg, K. M. and Boswell, A. E., 2000), mirroring the age-related improvement in detection-in-noise (Schneider, B. A. *et al.*, 1989).

If the immature auditory system exhibits a sluggish growth of response with increases in intensity or if the response at a given intensity is variable, detection and discrimination will be poor. Schneider B. A. *et al.* (1989) and Schneider B. A. and Trehub S. E. (1992) discuss the role of intensity coding in the development of detection in noise, but there is little direct evidence for immaturity of intensity coding in infancy or childhood. Cochlear responses tend to grow with intensity in a similar way in neonates and adults (Abdala, C., 2000). There are few studies that have compared infants and adults in the growth of neural evoked response amplitude with intensity, although response latency appears to change with increasing intensity in an adult-like fashion even in preterm infants (Gorga, M. P. *et al.*, 1989). Several studies (Durieux-Smith, A. *et al.*, 1985; Cornacchia, L. *et al.*, 1983; Rickard, L. K., 1988) have shown that

ABR wave V amplitude grows with increasing intensity more slowly in young infants, but the age difference did not persist beyond 10 months of age. Although auditory development of cortical evoked potentials clearly continues throughout childhood (e.g., Huttenlocher, P. R., 1979; Kraus, N. *et al.*, 1985; Sharma, A. *et al.*, 1997), the effects of age on the growth of cortical potentials with stimulus intensity has not been addressed. In fact, that infants are more mature in their detection of broadband than of narrow-band sounds, in the absence of any obvious bandwidth-dependent differences in attentiveness, suggests that intensity coding is not responsible for infants' immature detection in noise (Werner, L. A. and Boike, K., 2001).

3.50.2.2.3 Loudness

Given the relatively prolonged development of intensity discrimination performance, it is surprising that direct measures of loudness growth show few developmental effects beyond infancy (Bond, B. and Stevens, S. S., 1969; Collins, A. A. and Gescheider, G. A., 1989; Dorfman, D. D. and Megling, R., 1966). For example, Collins A. A. and Gescheider G. A. found that preschool children could not only perform a cross-modality loudness matching procedure, but that their results were quite similar to those of adults. It should be noted that this observation argues against immaturity of intensity processing in general, at least during the preschool period.

Interestingly, there is limited evidence for immaturity of loudness perception among infants. Leibold L. J. and Werner L. A. (2002) showed that infants, like adults, respond more quickly to a more intense tone. They found, further, that the rate at which response latency decreased with increasing tone intensity was greater in infants than it was in adults. In other words, loudness growth appeared to be more rapid in infants than in adults. This finding is difficult to reconcile with the idea that the neural response is growing more slowly with increasing intensity in young listeners. It is consistent with the idea that infants listen in a high level of internal noise: loudness grows more rapidly in external noise among adult listeners.

3.50.2.3 Temporal Resolution

Again, several observations of early auditory development in nonhuman species suggest that age-related changes in temporal resolution occur in the course of human development. Immature auditory neurons, for example, do not sustain response to continuous stimulation and demonstrate prolonged recovery from prior stimulation (e.g., Brugge, J. F. *et al.*, 1978). Whether the corresponding developmental period in humans occurs in the postnatal period is not clear.

Estimates of temporal resolution in infancy are heavily dependent on the measure used to assess temporal resolution. A popular measure has been the gap detection threshold, the shortest interruption in ongoing sound that can just be detected by the listener. Werner L. A. *et al.* (1992) measured gap detection thresholds in 3-, 6-, and 12-month-old infants and in adults for broadband noise and for low-pass noises with varying high-frequency cutoffs. Infants' gap detection thresholds were quite poor, on the order of 40–50 ms in the broadband noise condition. Gap detection threshold did not improve between 3 and 12 months of age, but changed with the frequency of the stimulus in a manner similar to that seen in adults. In subsequent experiments, Werner L. A. and her colleagues reported the same poor gap detection thresholds using a different method to estimate thresholds (Werner, L. A. *et al.*, 1994a) and showed that the effect of changing the stimulus frequency from gap onset to gap offset had similar effects on infants and adults (Werner, L. A. *et al.*, 1994a). Trehub S. E. *et al.* (1995) found that infants were better at detecting a gap between two Gaussian-shaped tone bursts than gaps in noise, but their gap thresholds were still far from adult-like. Studies of preschool children, on the other hand, generally indicated mature gap detection thresholds by 4 or 5 years of age (Wightman, F. *et al.*, 1989; Trehub, S. E. *et al.*, 1995).

Studies employing other measures of temporal resolution suggest a quite different pattern of development. Duration discrimination, for example, has been shown to be immature in infants and to remain immature in young children (Morrongiello, B. A. and Trehub, S. E., 1987; Elfenbein, J. L. *et al.*, 1993). Werner L. A. (1999), in contrast, reported that forward masking was adult-like by 6 months of age. While Buss E. *et al.* (1999) reported improvements in forward masked thresholds between 5 and 11 years, the improvement in masked threshold just paralleled the improvement seen in threshold in quiet. Thus, the amount of forward masking demonstrated at each age was about the same as that seen in adults. Finally, two developmental studies of the temporal modulation transfer function (TMTF) have been conducted. The TMTF shows the depth of modulation required to detect amplitude

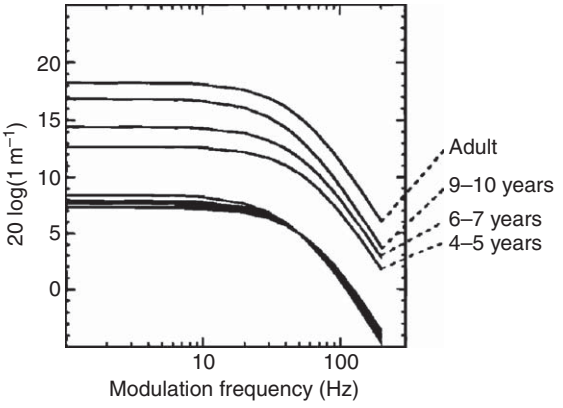

Figure 4 Temporal modulation transfer functions fit to the modulation detection data of four age groups. The functions are superimposed at the bottom of the panel to emphasize the similarity in shape. Reproduced from Hall, J. W. and Grose, J. H. 1994. Development of temporal resolution in children as measured by the temporal modulation transfer function. J. Acoust. Soc. Am. 96, 150–154, with permission.

modulation as a function of the modulation frequency. The TMTF has a low-pass characteristic and its cutoff frequency is a measure of temporal resolution (Viemeister, N. F., 1979). Both 3-month-old infants and 4- to 5-year-old children (Figure 4) appear to have adult-like TMTF (Hall, J. W. and Grose, J. H., 1994; Werner, L. A., 2006).

What conclusion can be drawn about the development of temporal resolution? On the basis of the TMTF, the gold standard of measures of temporal resolution, one would conclude that temporal resolution is mature quite early in life. This conclusion is consistent with several developmental physiological studies of temporal resolution: forward masking and gap detection in the ABR (Lasky, R. E., 1991; 1993; Werner, L. A. *et al.*, 2001) and in the mismatch negativity, a cortical evoked potential (Trainor, L. J. *et al.*, 2001) appear to be adult-like by 3 months postnatal age. An unanswered question is why infants and children have greater difficulty dealing with other temporally based tasks.

3.50.2.4 Spatial Resolution and Perception

3.50.2.4.1 Sound localization

Of all auditory capacities, spatial resolution would seem to be the most likely to undergo clear improvements with age because it depends on the size of the external ear and the head. Infants will certainly have a smaller range of interaural differences to work with, even if peripheral coding and the central circuits that calculate interaural differences are adult-like. In addition, the resonance of the small external ear will limit the frequencies that infants can use to localize sounds in elevation or to make front–back distinctions.

In fact, spatial resolution has been found to improve systematically with age, but to an extent that cannot be accounted for by peripheral immaturity alone. Newborn infants turn toward a sound source on their left or right (Clifton, R. K. *et al.*, 1981; Muir, D. and Field, T., 1979), but the minimum audible angle (MAA) at birth has been estimated at around 30° in azimuth (Morrongiello, B. A. *et al.*, 1994). The MAA in azimuth has been examined in infants and children in several laboratories; it has been reported to decrease from 30° at birth to about 14° at 7 months to adult levels at 5 years (Morrongiello, B. A. and Rocca, P. T., 1987a; 1990; Morrongiello, B. A. *et al.*, 1994; Litovsky, R. Y. and Ashmead, D. H., 1997; Clifton, R. K., 1992; Clarkson, M. G., 1995; Ashmead, D. H. *et al.*, 1987). However, sound localization probably continues to develop beyond the preschool period; for example, 5-year-olds' sound localization may be disrupted by the presence of sound reflections more than adults' (Litovsky, R., 1993).

Sound localization in elevation has been less well studied, although one laboratory has reported that the MAA in elevation for an 8–12 kHz noise band improved from nearly 16° at 6 months to about 6° at 18 months (Morrongiello, B. A. and Rocca, P. T., 1987c; 1987b). An interesting observation in these studies is that infants never achieve 75% correct in detecting a change in the position of a 4–8 kHz noise band or a 4 kHz low-pass noise. Adults also perform better in elevation discrimination if the stimulus contains frequencies above 4–5 kHz, but it appears that infants are more heavily dependent on frequencies above 8 kHz, which would be consistent with their smaller pinnas.

By 7 months of age, infants appear to discriminate differences in the distance to a sound source. Clifton R. K. and her colleagues (1991) developed a clever procedure to allow infants to demonstrate their ability to judge the distance of a sounding object. After allowing the infant to play with a sounding object in the light, these researchers presented the same sounding object to infants at varying distances in the dark. Infants were found to reach more often for the object when it was within their reach than when it was beyond their reach. Litovsky R. and Clifton R. K. (1992) subsequently showed that infants did not

depend solely on the sound pressure level arriving at their head to perform this discrimination; they continued to reach more to within-reach than to beyond-reach objects even when the intensity of sound was varied randomly. Interestingly, adult subjects tested in a similar situation appeared to be more heavily dependent on sound pressure level in making distance judgments.

Several attempts have been made to explicate the mechanisms responsible for age-related improvements in sound localization. Potential candidates include acoustic cues, peripheral coding, neural calculation of interaural differences and spectral shape, and the central mapping of acoustic cues onto positions in space. Clifton R. K. *et al.* (1988) addressed the issue of changes in the acoustic cues available for localization by directly measuring interaural distance and head circumference in neonates and 22-week-olds. From these measurements, they estimated that the maximum interaural time difference (ITD) available to infants would increase from 400 to 500 μs over this age period. If infants depended only on interaural time differences to locate sounds in azimuth, they should be able to achieve an MAA less than 10° at this age, compared to the 20° observed (Ashmead D. H. *et al.*, 1987). Ashmead D. H. *et al.* (1991) followed the development of ITD discrimination from 16 to 28 weeks of age. ITD discrimination thresholds were on the order of 50–75 μs, were never poor enough to account for the infant's immature MAA, and did not improve with age as the MAA does. This suggests that maturation of neither the precision of temporal information provided by the ear nor the function of the neural circuits involved in ITD calculation can entirely account for the maturation of spatial resolution in azimuth. Gray L. (1992) has argued that changes in chicks' responses to changes in the location of a sound source in the first few days after hatching reflect the acquisition of an organized representation of auditory space. Observations of humans who are congenitally deprived of binaural input support the idea that this mapping process is an important aspect of the development of sound localization. These individuals achieve respectable performance in ITD discrimination when surgical intervention makes binaural hearing possible for them, but they continue to have quite poor abilities to identify the location of a sound source in space (Wilmington D. *et al.*, 1994). These observations in humans are consistent with many studies of the effects of abnormal binaural experience on the development of spatial hearing in other species (e.g., Moore D. R., 1983; Knudsen, E. I., 1988; Binns, K. E. *et al.*, 1995).

3.50.2.4.2 Binaural masking level difference and spatial release from masking

One advantage of binaural hearing is the improvement in sensitivity to target sounds that results when target and competing sounds are perceived as coming from different spatial locations. In the laboratory, one form of this advantage, the binaural masking level difference (BMLD), has been extensively studied. Compared to the condition in which the same masker and tone are presented under earphones to both ears (designated N_0S_0), threshold for a tone presented in a broadband masker is as much as 15 dB lower when the same masker is presented to both ears, while the tone is presented 180° out of phase at one ear relative the other (designated N_0S_π). The BMLD is the threshold improvement observed under such dichotic conditions.

Given the dramatic improvement in auditory spatial resolution during infancy and early childhood, it is of some interest whether similar improvements are evident in the BMLD. To the extent that the same mechanisms are involved in calculating the interaural time difference that underlies both sound localization and the BMLD, one might predict that the two follow similar developmental courses. At first blush, this appears to be the case. Nozza R. J. (1987) and Nozza R. J. *et al.* (1988) have reported, that under conditions that produce a BMLD of about 11 dB for adults, 7-month-old infants have a BMLD of only 5 dB. Nozza R. J. *et al.* concluded that preschool children were probably adult-like in BMLD, but Hall J.W. and Grose J. H. (1990) subsequently found that while 6-year-old children had adult-like BMLD, 4- to 5-year-old children still had somewhat smaller BMLD than adults. In all cases, the reduced BMLD resulted from a relatively higher threshold in the N_0S_π condition, suggesting immaturity of binaural processing.

In several studies, however, Hall J.W., Grose J. H. and colleagues (Grose, J. H. *et al.*, 1997; Hall, J. W. and Grose, J. H., 1990; Hall, J. W. *et al.*, 2004) have found that while school-age children have adult-like BMLD for a broadband masker, they have significantly smaller BMLD for narrow-band maskers. Adults seem to be able to take advantage of low-energy segments of the fluctuating envelope of a narrow-band masker in binaural detection (i.e., by listening in the dips). One explanation for the

developmental trend observed in the BMLD for narrow-band maskers is that children are less able than adults to use this additional information. This idea is consistent with an observation by Litovsky R. Y. (2005) that school-age children were unable to take advantage of spatial separation of speech target and masker in free field when the masker is the voice of a single speaker, although they did show spatial release from masking in other masking conditions. In the single-speaker masking condition, listeners have a particular opportunity to use gaps in the masker to hear the target.

Thus, infants appear to have immature binaural processing. Given little evidence that intensity or temporal coding is immature at 7 months, this finding is consistent with a central processing immaturity. By age 5 or 6 years, children appear capable of using binaural information under many conditions, but under more difficult listening conditions, adults are able to access additional cues that children do not.

3.50.3 Development of Complex Perceptual Capacities

Mature processing of complex sounds in real environments requires more than a simple representation of the spectral and temporal characteristics of the acoustic stimulus. Because sound from multiple sources is generally present, the listener is required to group the components of each complex sound according to its source and to select the sound from the appropriate source for further processing. Furthermore, within the complex arising from any one source, some frequency bands or temporal segments may be more informative than others, and thus be more heavily weighted in the process of recognition or identification. An important point is that immaturity of processes such as sound source determination, selective attention, and listening to relevant sound features is likely to manifest itself in many ways, including apparent immaturity of intensity resolution or listening efficiency. Because primary auditory processes appear to be relatively mature during infancy, we tend to believe that it is these complex, higher-level auditory processes that limit the performance of infants and children, even in simple listening tasks.

The idea that infants and children are just not as good as adults in performing psychophysical tasks is one that occurs to even the casual student of sensory development. In psychophysical terms, infants and children are inefficient listeners. Efficiency is influenced by primary auditory processes, but also by a variety of factors such as memory, attention, and motivation. Both resolution and efficiency influence sensitivity. An inefficient listener is less sensitive to a tone in noise, and one would expect that inefficiency to carry over into the perception of any sound in a noisy background. Many investigators have suggested that infants and children are inefficient listeners compared to adults (Allen, P. and Wightman, F., 1994; Bargones, J. Y. *et al.*, 1995; Hartley, D. E. H. *et al.*, 2000; Werner, L. A. and Boike, K., 2001). The sources of early immature efficiency, however, are not well understood. In this section, possible contributions of higher-level perceptual processes to the development of auditory sensitivity are considered.

3.50.3.1 Sound Source Determination

By sound source determination is meant the process by which a listener segregates the components of complex sound into different auditory objects. For example, listeners are able to take sound emanating simultaneously from the voice of a conversant, a barking dog, and a passing car and to parse the complex into three different sound sources despite the fact that there is spectral and temporal overlap among the three sounds. Listeners use many types of information to accomplish this task, considering common temporal modulation, location, and harmonicity among others. In the lab, a common approach to studying sound source determination is auditory streaming, in which a listener is asked to report the number of separate sound sources heard in a complex sound and sometimes to describe each source. Because infants and young children have difficulty understanding such procedures, researchers have had to develop more indirect measures of sound source determination in young listeners.

It is clear that infants can segregate sound sources under some conditions. Newman R. S. and Jusczyk P. W. (1996) exposed 7- to 8-month-old infants to two superimposed voices, one male and one female. The female voice spoke a series of words with exaggerated intonation, while the male voice recited text from the methods section of a journal article. Following 30 s exposure, infants were presented with a list of words spoken by the same female voice whenever they looked at a flashing light. On some trials, the words were the same words spoken in the initial exposure; on others, the words were novel.

If infants looked longer for one list of words than the other, it was concluded that the infants recognized the words they had heard in competition with the male voice. If the female voice was presented at a level 5 or 10 dB greater than that of the male voice, infants looked longer for the word list previously presented, but if the levels of the two voices were equal, they showed no evidence of recognizing the words. This study certainly indicates that under some circumstances, infants are capable of segregating two competing voices. However, it suggests that even when the two voices differ in fundamental frequency, timing, and intonation, infants have difficulty segregating the two voices without an additional intensity difference. Because adult's speech reception thresholds under similar conditions would be well below 0 dB signal-to-noise ratio (e.g., Litovsky R. Y., 2005), the acoustic components of the target words were presumably audible to both infants and adults. Beyond that, infants' failure to respond differentially to the familiar words at 0 dB signal-to-noise ratio could result from a failure of sound source determination, a failure of selective attention, or both. Although it does not resolve this issue, a recent study by Hollich G. *et al.* (2005) showed that infants did recognize the words in the target voice when the competing voice was of equal intensity, if presentation of the voices was accompanied by a video of the talker's face.

Several investigators have attempted to study auditory streaming in infants using other approaches. Adult listeners have difficulty judging the relative order of elements of sound that are perceived in separate auditory streams. Thus, if the order of sounds in a sequence is reversed, the listener's ability to discriminate the change in order will depend on whether or not the sounds are heard in the same auditory stream (Figure 5). Demany, L (1982), Fassbender C. (1993), and McAdams S. and Bertoncini J. (1997) have all demonstrated that infants' ability to discriminate a change in the order of a sound sequence changes in a way that is consistent with adults' stream segregation. However, the limits of the infants' ability to form auditory streams and the relative importance of different acoustic cues in determining how infants form streams remain unexplored.

It is curious that auditory streaming experiments with older children have not been reported, because it is quite possible that even preschool children would be able to perform some version of the auditory streaming task. The question of sound source determination in children has been addressed indirectly in studies of co-modulation masking release (CMR). Adults detect a tone at a lower intensity if intensity fluctuations in sounds in frequency bands away from the tone frequency match the fluctuations in the intensity of a masker centered on the signal frequency. Adults' thresholds for the tone are actually

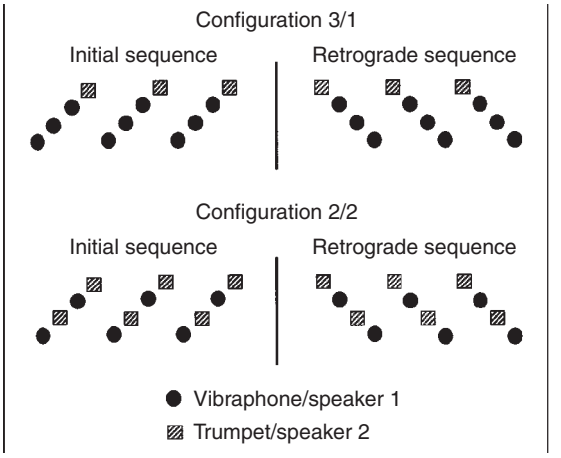

Figure 5 Examples of stimulus sequences used in an auditory streaming experiment with infant subjects. The vertical dimension in each panel is fundamental frequency. The circles represent synthetic vibraphone tones that were played from a speaker to one side of the infant's head. The squares represent trumpet tones that were played from a speaker on the opposite side of the infant's head. Adults listening to both sequences reported hearing two auditory streams. In the top panel, a slowly repeated trumpet tone was heard in one stream, while, in the other, a descending ('initial sequence') or ascending ('retrograde sequence') series of faster vibraphone tones was heard. In the bottom panel, a series of alternating high and low vibraphone tones was heard in one stream, while, in the other, a slightly lower alternating high and low sequence of trumpet tones was heard. When the initial sequence in the top panel was played in reverse, adults could discriminate the change. In the bottom panel, if adults had heard the sound as a single stream, they would be able to discriminate the initial sequence from its reverse, because the pitch would now decrease, rather than increase, across each repetition of the four-tone sequence. However, when the adults heard the stimulus as two streams, the same alternating high–low sequence could be heard whether the sequence was played forward or backward. Infants listening to these two stimulus configurations discriminated the initial sequence in the top panel from its retrograde, but showed no evidence of discriminating the initial sequence in the bottom panel from its retrograde. The latter result suggests that infants heard the sequence in the bottom panel as two auditory streams, as adults did. Reproduced from McAdams, S. and Bertoncini, J. 1997. Organization and discrimination of repeating sound sequences by newborn infants. J. Acoust. Soc. Am. 102, 2945–2953, with permission.

higher if no sounds other than the masker centered on its frequency are present. This phenomenon is referred to as CMR (Hall, J. W., 1987). CMR is thought to reflect processes important to sound source determination: the signal tone may be more audible if the on-signal masker is perceptually grouped with the other flanking noise bands. Grose J. H. *et al.* (1993) reported that 4-year-old children showed the same threshold improvement from adding off-frequency, co-modulated frequency bands as adults do. Hall J.W. *et al.* (1997) found that slightly older children also exhibited adult-like CMR, but reported that when the masker band centered on the signal frequency and the off-frequency co-modulated bands were slightly asynchronous, adults' CMR was reduced while children's CMR was eliminated or became negative. One possible explanation for this result is that temporal synchrony is a more important grouping factor for children than it is for adults.

3.50.3.2 Auditory Attention

The development of two varieties of attention is considered here. The first is attentiveness, often referred to as sustained attention. By attentiveness is meant the ability to remain 'on task' and to acquire information about the stimulus. The other, probably more important sort of attention will be referred to as selective attention. Once incoming sound has been parsed into separate auditory objects, a listener must frequently choose the sound from one source for further processing while ignoring others. Further, some features of sound from a single source may be processed while others are not. These processes require auditory selective attention. It should be noted that any complex listening task involves the basic analytic processes that underlie all hearing. Then the components belonging to a single source must be identified and integrated, and finally, one source selected for processing. Failure to selectively process a sound, then, will occur if any of these processes – analysis, sound source determination, selective attention – is immature. On the basis of the studies reviewed above, we conclude that the basic analytic processes are mature by 6 or 7 months of age, but while several studies have attempted to study selective auditory attention, immature sound source determination could well have influenced children's performance in these studies.

3.50.3.2.1 Attentiveness

An obvious reason that infants and children perform rather poorly in some psychophysical tasks is that they have difficulty sustaining attention to the task. Inattentiveness may prevent them from having any idea whether or not a tone was presented on some trials, for example. Several investigators have argued that while infants and children are undoubtedly inattentive at some points during testing, the effects of inattentiveness would not be expected to be large enough to account for the observed age differences in auditory sensitivity (Schneider, B. A. and Trehub, S. E., 1992; Viemeister, N. F. and Schlauch, R. S., 1992; Werner, L. A. and Bargones, J. Y., 1992; Wightman, F. and Allen, P., 1992). In studies that have examined the psychometric function for detection, the upper asymptote of the function has been reported to be less than 1 for many infants and children (Allen, P. and Wightman, F., 1994; Bargones, J. Y. *et al.*, 1995; Werner, L. A. and Boike, K., 2001). This is consistent with inattentive listening: even when the sound is audible, young listeners respond incorrectly on some trials. If one assumes that the listener has no information about the stimulus on inattentive trials and that on such trials the listener guesses whether or not a signal occurred, then the rate of inattention would be twice the difference between 1 and the observed upper asymptote. In infants, the inattention rate is estimated at about 30% in a variety of conditions (Bargones, J. Y. *et al.*, 1995; Werner, L. A. and Boike, K., 2001), and, in children, it appears to range from 0% to 25% (Allen, P. and Wightman, F., 1994). Further analyses show, however, that even an inattention rate of 30% would shift the observed threshold for detecting a tone by only 2–3 dB. Similarly small effects would be expected in other tasks. In no case is the effect of inattentiveness sufficient to account for the observed difference between adults and infants and children.

3.50.3.2.2 Selective listening to relevant sound features

Another explanation for early immature psychoacoustic performance is immature listening strategies. Adults tend to listen at expected frequencies and at times when a sound could be presented. Adults quickly discover and focus on the most informative cues in a complex stimulus. Infants, on the other hand, may listen in a less selective fashion. Werner L. A. and Bargones J. Y. (1991), for example, showed that 7-month-old infants' threshold for a tone were elevated by the presence of a higher frequency

masker well removed from the frequency region of the tone. Adults tested under the same condition demonstrated little or no masking. Bargones J. Y. and Werner L. A. (1994) subsequently showed that while adults were more sensitive to a frequency they expected to hear than to other unexpected frequencies, infants were equally sensitive to expected and unexpected frequencies. Thus, adults appear to restrict listening to the frequency band around the signal they are trying to detect, while infants listen broadly across frequencies regardless of the signal to be detected. It has been estimated that failure to monitor the frequency band around the to-be-detected signal would increase threshold by about 7 dB (Dai, H. *et al.*, 1991), which would account for a large portion of the difference between infants' and adults' thresholds for a tone in noise (Werner, L. A. and Boike, K., 2001).

Preschool children have not yet become consistently selective listeners. Stellmack M. A. *et al.* (1997) asked 5-year-olds and adults to discriminate changes in intensity in one component of a three-component complex. If the level of the 'distractor' components was lower than that of the target, both children and adults were able to listen selectively to the target component. In contrast, if the target and distractors were equal in level, only the adults were able to continue to listen selectively to the target. It should be noted, however, that even when the task was to discriminate overall intensity differences between three-component complexes, 5-year-olds needed larger intensity differences to perform the task than adults did, despite the fact that selective listening was not the optimal strategy (Willihnganz, M. S. *et al.*, 1997).

Even infants may be able to listen selectively in time, however. Parrish H. K. and Werner L. A. (2004) tested infants' ability to detect a tone that occurred following a short noise burst that indicated the beginning of a trial. On most trials, the tone occurred 500 ms after the noise burst, but on a small proportion of trials, the tone occurred 200 or 800 ms after the noise burst. Under these conditions, both infants and adults detected the tone at 500 ms better than the tone at 200 or at 800 ms, and the effect of presentation time was no different for the two age groups. Thus, it would appear that listening broadly over time does not contribute to infant–adult threshold differences.

Another developmental effect that may be important in somewhat more complex listening situations is a shift in the cues used to detect or discriminate sounds. One example is the observation of Hall J.W. and Grose J. H. (2004) discussed above, that children do not take advantage of temporal fluctuations in the level of a masker to detect a signal. Similarly, infants and children may focus on salient aspects of a sound, but ignore additional cues that may allow them to discriminate between sounds under more difficult listening conditions. For example, Lacerda F. (1992) found that infants younger than 5 months of age were more likely to respond to a change in a formant transition in a CV syllable, while adults labeled the syllables primarily on the basis of vowel quality. Nittrouer S. and her colleagues (Nittrouer, S. and Studdert-Kennedy, M., 1987; Nittrouer, S. and Boothroyd, A., 1990; Nittrouer S., 1996; Nittrouer, S. and Miller, M. E., 1997; Nittrouer, S. and Crowther, C. S., 1998; 2001; Nittrouer, S. *et al.*, 1998) have completed a series of studies of preschool and school-age children that demonstrate that they, too, are more influenced by formant transitions than by static cues in identifying consonants. Recently, Nittrouer S. (2005) has suggested that young children's differential attention to dynamic cues in speech may make it more difficult for them to identify speech in noise.

3.50.3.2.3 Ignoring irrelevant sound features

Informational masking is defined here as a reduction in the audibility or discriminability of one sound that results from the presence of another sound, beyond that accounted for by overlap of the excitation patterns of the two sounds in the auditory periphery. Although there is currently some controversy over the meaning of informational masking (e.g., Durlach, N. I. *et al.*, 2003), this definition captures the generally agreed upon features of the phenomenon. In a paradigm that has been used in many subsequent studies, Neff D. L. and Green D. M. (1987) showed that detection threshold for a tone was elevated over quiet threshold when the frequencies of a competing multicomponent complex varied randomly from trial to trial, even though the frequencies in the competing complex were well outside the auditory filter centered on the target frequency. Essentially, informational masking results from a failure to ignore the resolvable competing components (Lutfi, R. A. *et al.*, 2003). There are large individual differences among adults in the amount of informational masking demonstrated, but in general, the greatest amount of masking is seen with ten-component competing complexes (e.g., Neff, D. L. and Callaghan, B. P., 1988). Allen P. and Wightman F. (1995) first demonstrated

that preschool children's threshold for a pure tone in noise was increased by more than 24 dB if one other random frequency tone was presented simultaneously, compared to 11 dB for adults. Moreover, half of the children Allen P. and Wightman F. tested were unable to detect the target tone at an intensity less than 90 dB.

Oh E. L. *et al.* (2001) obtained thresholds for a 1000 Hz tone from preschoolers and adults in broadband noise and in the presence of tonal complexes with 2–1000 randomly drawn components. Children demonstrated somewhat more masking than adults in the broadband noise masker, but 25–35 dB more masking than adults when the masker components varied randomly. Children were qualitatively similar to adults in that they demonstrated the most informational masking in the ten-component masker condition, but were more likely than adults to exhibit significant masking in the presence of a two-component masker. The results were well described by a model (Lutfi, R. A., 1993) in which children monitor a greater number of auditory filters than adults do, consistent with previous studies of infants and children (Allen, P. and Wightman, F., 1994; Bargones, J. Y. and Werner, L. A., 1994; Bargones, J. Y. *et al.*, 1995; Werner, L. A. and Boike, K., 2001).

Leibold L. J. and Werner L. A. (2006) compared 7–9-month-olds' and adults' detection of a 1000 Hz tone in the presence of three different maskers, a broadband noise, a random-frequency two-tone complex and a fixed-frequency two-tone complex. Neither of the two-tone complexes had energy around 1000 Hz. Adults' thresholds were 15 dB higher, while infants' thresholds were 23 dB higher, with the random frequency masker than with the broadband noise masker, suggesting more informational masking with the random frequency masker. It is not clear why children appear to perform more poorly than infants, relative to adults, in informational masking (cf., Oh, E. L. *et al.*, 2001 described earlier). Interestingly, adults' thresholds were 37 dB higher, while infants' thresholds were just 33 dB higher, with the fixed-frequency two-tone masker than with the random-frequency two-tone masker. On this basis, it is not clear at all that infants are more susceptible to random-frequency masking effects than adults are.

A related question is whether manipulations that reduce informational masking in adults have similar effects on children. For example, gating a random-frequency masker prior to the onset of the target tone tends to reduce the amount of informational masking, as does repeating the target several times while the random-frequency masker varies (Hall, J. W. *et al.*, 2005; Kidd, G. *et al.*, 1994). Hall J. W. *et al.* reported that children tended to derive less benefit in detection from such manipulations than adults do, but it was not clear whether the ability to do so improved between 5 and 9 years of age. Another manipulation that reduces informational masking in adults is a spatial difference between the random-frequency masker and the target tone, for example, by presenting the masker and target to different ears or to speakers located in different spatial positions (Neff, D. L., 1995; Kidd, J., G. *et al.*, 1998; Arbogast, T. L. *et al.*, 2002). Two different laboratories have now demonstrated that 4- to 9-year-old children do not show a spatial release from informational masking and may even show increased masking when the masker and target are presented dichotically (Hall, J. W. *et al.*, 2005; Wightman, F. *et al.*, 2003).

3.50.3.2.4 Listening to competing messages

Dichotic listening is the classic paradigm for the study of selective auditory attention (Cherry, E. C., 1953): a listener is presented with two sound sequences. In one condition, the sequences are presented simultaneously to the same ear(s). In the other, one sound sequence is presented to one ear and a different sound sequence to the other. The sound sequences are typically speech. The listener is asked to report the sound presented in one sequence, while ignoring the other. Maccoby E. E. and Konrad K. W. (1966) tested kindergarten, second-grade, and fourth-grade children in such a selective listening task. In the dichotic condition, a male voice spoke words in one ear, while a female voice spoke words in the other. In the diotic condition, both voices were presented to both ears. Children were instructed to report the word spoken by either the male or female voice. Performance in the diotic condition was rather poor overall, but improved from 18% to 33% correct between kindergarten and fourth grade. In the dichotic condition, performance was uniformly better at all ages, but still improved from 35% to 52% correct over the age range tested. Doyle A.-B. (1973) reported that the improvement in performance in the diotic competing message condition continued to a lesser extent between 8 and 14 years of age. The results of more recent studies are consistent with this pattern, and indicate that differences between event-related potentials evoked by attended and unattended stimuli increase in parallel with performance in

dichotic listening tasks (Bartgis, J. *et al.*, 2003; Berman, S. and Friedman, D., 1995; Coch, D. *et al.*, 2005).

Recent studies of children disentangling competing messages have produced a wide range of results. For example, Litovsky R. Y. (2005) asked 4- to 7-year-olds and adults to identify spondees in the presence of 1- or 2-talker speech or of speech-shaped noise modulated with the 1- or 2-talker speech envelope. Children's thresholds were higher than adults' in all conditions, but: (1) the amount of masking exhibited by children and adults was similar in all conditions; (2) both children and adults had higher speech reception thresholds in modulated speech-shaped noise than in speech; and (3) children and adults showed equivalent release from masking when the spondee was presented from the speaker in front of the listener and the competing sound was presented to a speaker on the listener's right. Fallon M. *et al.* (2000) reported that 5-year-olds were as good as adults in identifying words in a background of multitalker babble, as long as age differences in masked thresholds were taken into account. Hall J.W. *et al.* (2002), in contrast, found that while adults' spondee identification was about the same with two-talker and noise maskers, 5- to 9-year-old children's spondee identification was worse with a two-talker masker than with a noise masker, particularly when the speech masker was presented continuously throughout the session. Finally, Wightman F. and Kistler D. (2005) asked children and adults to identify speech in a paradigm developed by Brungart, D. S. and his colleagues (Brungart, D. S., 2001). Listeners heard a target sentence along with a competing sentence in one ear, and in one condition, an additional competing sentence or a modulated speech-shaped noise was presented in the other ear. Listeners ranging in age from 4.6 to 30 years were tested with a female-talker distracter. The youngest children, 4.6–5.7 years old, needed a 23 dB greater signal-to-distracter ratio than 20- to 30-year-olds to identify a word in the target sentence when no contralateral distracter was presented. Adding noise to the contralateral ear had little effect at any age, but adding speech to the contralateral ear had a greater effect on the youngest children than on other age groups. Older children seemed to be affected by the presence of contralateral speech to about the same extent as adults.

It is difficult to draw conclusions about the development of selective attention from these studies. Several variables seem to be important in determining whether children will be able to attend selectively to one of several competing messages. One of these is the extent to which the target and distracters are synchronized in time. In the Wightman F. and Kistler D. (2005) experiment, for example, the words in the target and distracter stimuli were precisely aligned. Temporal synchrony is one variable that makes it difficult for listeners to segregate sound sources (Yost, W. A., 1991).

It is interesting that in the speech studies in which the words in the target and distracter sentences were not precisely aligned, children are generally able to take advantage of differences in spatial location to improve performance, while in informational masking studies where target and distracter are temporally aligned, they are not. This suggests a problem with sound source segregation rather than with selective attention. The precise characteristics of the distracter also seem to be important. For example, if children are less able than adults to take advantage of periods of low distracter energy to process the target, then more modulated distracters (e.g., single-talker versus multitalker) will put children at a relative disadvantage compared to adults. Finally, it does appear that children may less easily ignore the semantic content of the distracter than adults. Hall J.W. *et al.* (2002) reported that children's spondee identification was more disrupted by continuous speech (in which the listener might follow the meaning) than by gated speech (in which the semantic content would be disrupted by gating), while gating the distracter made little difference to adult performance. A similar result was reported by Cherry E. C. (1981). Considerably more research will obviously be needed to understand the development of auditory attention.

3.50.4 Summary and Conclusion

Postnatal auditory development in humans appears to occur in two stages. In the first six months of life, maturation of the conductive apparatus and of the primary neural pathways results in substantial improvement in absolute sensitivity and frequency resolution, especially at high frequencies. The challenge for future research in this area is to develop approaches that allow us to understand the nature of these early changes and their impact on early perceptual learning.

After six months of age, perceptual performance remains immature, however, despite the fact that intensity, frequency, and temporal processing are

nearly adult-like. Auditory perception continues to improve into childhood and adolescence. Development over this prolonged period involves maturation of perceptual organization and attentional processes, but also learning about the important features of sound through experience. The challenge in understanding development in this later period is to develop approaches that will allow us to disentangle the effects of the many perceptual processes involved.

Glossary

auditory feedback The sound perceived of one's own vocalization.

consolidation An active offline process that serves to increase the stability of a memory.

declarative memory Explicit memory, such as for facts or concepts.

deconsolidation An active offline process that serves to decrease the stability of a memory.

generalized learning Deriving categories from learning explicit items/instances, hence applying the learning to categorize newly encountered items/instances.

nondeclarative memory Implicit memory such as procedural memory.

offline processing Information processing related to a task that occurs after the task and associated feedback are completed.

procedural memory A memory for performing a task.

neuronal replay Neural activity, typically emitted spontaneously in the absence of a behavior, that nevertheless matches the neural activity observed during the behavior.

sensorimotor learning Motor learning that involves sensory feedback.

tutor song The song that a juvenile bird commits to memory as a guide for further song development.

3.51.1 Introduction

The role of the unconscious, specifically the impact of dreaming, on our conscious life has been the subject of speculation through millennia of human thought. Sleep provides a state during which information acquired during the day may be reprocessed without competition from other stimuli, and this processing may reflect the consolidation of memory. Empirical evidence that waking events are replayed during dreaming (Stickgold, R. *et al.*, 2000b) and theoretical work on learning and unlearning in neural networks (Crick, F. and Mitchison, G., 1983; Hinton, G. E. *et al.*, 1995) provides support for this view. Although there remains considerable ignorance concerning the functional significance of sleep stages, as well as considerable controversy regarding specific hypotheses such as the rapid eye movement (REM)-consolidation hypothesis (Siegel, J. M., 2001), it is now well established that sleep makes a significant contribution to a broad range of learning tasks (Walker, M. P. and Stickgold, R., 2006). In animals, the neurophysiological mechanisms of how sleep influences natural behavior is being elaborated (Sutherland, G. R. and McNaughton, B., 2000). In this chapter, we review how sleep interacts with several forms of memory acquisition. Our principal focus is on auditory tasks in humans and animals.

Sleep is thought to influence learning through its effect on memory consolidation, the processing of the memory trace after its initial formation (memory acquisition) but while the memory remains in a labile state. Sleep was traditionally believed to passively to protect memory against loss, a quiescent state preventing new information from interfering with prior learning (retroactive interference) (Jenkins, J. M. and Dallenbach, K. M., 1924). However, neither sleep nor memory formation is a unitary process, indicating that consolidation must describe a broad range of phenomena. For example, there is compelling evidence that the action of sleep to deconsolidate vocal behavior is a regular feature of vocal development (Deregnaucourt, S. *et al.*, 2005), a major focus of this chapter.

Sleep is one of several physiological states during which offline processing occurs. Offline processing comprises the processing of information after the completion of a task (i.e., changes in representations) and after explicit feedback regarding the task has occurred, and cannot occur when an animal is engaged in another task (Foster, D. J. and Wilson, M. A., 2006). Thus, resting wakeful states (Gottselig, J. M. *et al.*, 2004) and naps (Mednick, S. C. *et al.*, 2002; 2003; Gomez, R. L. *et al.*, 2006) should also contribute to memory consolidation.

3.51.2 Sleep and Memory Consolidation in Humans

The way in which sleep affects memory depends on the type of memory being studied. Memory is traditionally divided into two systems, declarative and nondeclarative, or procedural, memory (Squire, L., 1987). The formation of declarative memory, or memory for facts, concepts, or information that can be explicitly recalled, is mediated by medial temporal lobe structures, particularly the hippocampus and surrounding areas (Mishkin, M. 1978; Zola-Morgan, S. *et al.*, 1993). A role of sleep in declarative memory consolidation has been elusive (Smith, C., 2001) and has been only recently elucidated with the demonstration that memory for paired associated word lists is enhanced more after a period of slow wave sleep (SWS) than an equal duration of REM sleep or waking (Plihal, W. and Born, J., 1997; Gais, S. and Born, J., 2004). After sleep, memory is less susceptible to retroactive interference than after an equal interval of waking (Ellenbogen, J. M. *et al.*, 2006), suggesting that sleep normally protects memories formed 1 day from associative interference of new information acquired on subsequent days.

Nondeclarative memory is memory for a procedure for accomplishing a task, and also includes simple habituation, sensitization, or conditioning. Formation of nondeclarative memory generally relies on task-dependent cortical and subcortical structures and does not always involve the hippocampus or medial temporal lobe (Milner, B., 1965). There is considerable evidence that sleep enhances nondeclarative memory consolidation in simple task acquisition. In a rote motor sequence-tapping task, performance improved after sleep but not after an equivalent period of waking (Walker, M. P. *et al.*, 2002; 2003). In a visual texture discrimination task, performance declined throughout training; improvement over baseline was seen only after sleep and was blocked by sleep deprivation followed training (Stickgold, R. *et al.*, 2000a; 2000c). REM sleep is essential for nondeclarative learning in the visual texture discrimination task: REM sleep deprivation following learning prevents performance improvement, whereas SWS deprivation has no effect on learning (Karni, A. *et al.*, 1994). Thus, sleep has two distinct effects on nondeclarative memory. Either,

performance improves after training and remains stable throughout the day, with additional performance gains are found following a night of sleep (cf. Walker, M. P., 2005a; 2005b), or performance declines throughout training and improvement over baseline performance requires sleep (cf. Stickgold, R., 2000a; 2000c). The origin of these disparate effects remains unclear.

3.51.2.1 Consolidation in Generalized Learning

Whereas the declarative/nondeclarative distinction is a useful way to divide memory, recent research has identified additional dimensions relevant to memory formation and consolidation. Memory may record specific details of an experience but retrieval may bring forth either the particular or some level of abstraction (e.g., McClelland, J. L. and Rumelhart, D. E., 1985). Learning may produce improved performance on particular items as in rote memory or may enable generalization to new items that have not been encountered. Generalized learning is a hallmark of adaptive behavior.

Sleep interacts with generalized learning. When individuals were given a relatively complex algorithm that could be solved using a hidden rule, the ability to generalize information to apply this rule was more likely to appear after sleep than after a day (or night) awake (Wagner, U. *et al.*, 2004). Learning can promote faster performance on each individual step or it can lead to the discovery of hidden rules that promote faster performance on the entire problem (but does not affect performance on the individual steps). Finding hidden rules requires the ability to flexibly use the information given during training to develop an alternate solution. After sleep, the memory representation has been restructured to produce this abstraction.

In generalized sensorimotor learning, sleep both inoculates memory against subsequent loss and also restores performance levels that were reduced at the end of a waking interval. Individuals trained in a video game task showed improved performance, but a waking interval resulted in a loss of some of this learning that was then restored by sleep (Brawn, T. *et al.*, 2006). Sleep shortly after training prevented the loss. It remains unclear which aspects of the learning are lost by the end of the day and whether sleep restores the aspects of learning that are lost during the day or improves performance on different aspects of the task.

3.51.2.2 Auditory Memory Consolidation

The diverse effects of sleep on memory have been observed in a variety of auditory tasks. In rote tone discrimination memory, a waking interval stabilizes performance gains achieved after training. Sleep enhances this memory, with additional improvement appearing after a night of sleep (Gaab, N. *et al.*, 2004). Whereas this pattern of waking stabilization and sleep-dependent enhancement is similar to that found for rote motor memory, it is not found for generalized auditory learning or for other rote auditory tasks. For example, performance in an auditory tone sequence learning task significantly improved both after sleep and after an equal period of quiet waking in which no external stimuli were administered. However, performance did not improve if new information was presented in the waking interval, illuminating its susceptibility to retroactive interference (Gottselig, J. M. *et al.*, 2004). Similar waking-consolidation effects were also found for an auditory oddball paradigm. This task required the detection of a deviant tone sequence within a series of repetitions of a standard sequence. The two eight-tone sequences differed only in the frequency of the sixth tone. In this task, continued behavioral enhancement occurred for three nights following training, even if sleep-deprivation occurred on the first night (Atienza, M. *et al.*, 2004), further demonstrating consolidation without sleep.

Consolidation in generalized auditory memory shows a similar pattern to consolidation of complex sensorimotor learning (Fenn, K. M. *et al.*, 2003). In a perceptual language learning task, subjects were trained and tested on monosyllabic words that were produced by a speech synthesizer. Learning to generalize linguistic categories from the novel acoustic patterns (as was required by the experimental design) was robustly consolidated by sleep (Figure 1). After a relatively brief period of training, performance increased from about one-third words correctly identified to about one-half of words correctly identified. For subjects trained in the morning, roughly half of the performance increase was lost by the evening, but remarkably the original level of posttraining performance was restored after a night's sleep. Performance degradation did not occur on subsequent days.

Sleep has been shown to affect generalization in a linguistic task in infants. Using a statistical learning paradigm (cf. Saffran, J. R. *et al.*, 1996) in which auditory strings adhering to a simple rule were presented, a nap was found to qualitatively change the memory representation such that the infants generalized

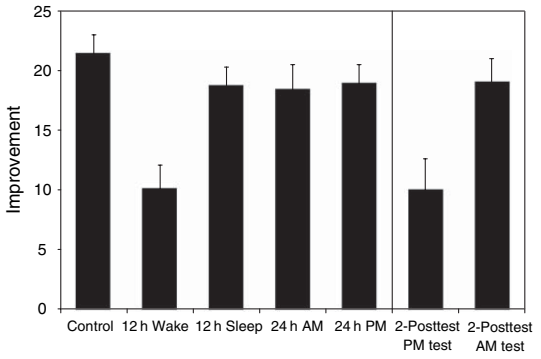

Figure 1 Effects of sleep on generalized speech learning. Change in percent correct from pretest to posttest in a generalized speech learning task when tested immediately after training (Control), after a 12 h waking interval (12 h Wake), after a 12 h interval that included a regular sleep phase (12 h Sleep), or after a 24 h interval with testing in the morning (24 h AM) or evening (24 h PM). The final two bars represent data from the same group of subjects, replicating the effects observed in the between-subjects comparison. The first bar indicates amount of improvement after a 12 h waking interval and the second bar indicates improvement when tested 12 h later, after a regular sleep phase.

beyond the trained stimuli. In this task, the stimuli were three-element spoken sequences in which the initial and final elements were predictive of one another, whereas the middle item could vary. Learning could be achieved by remembering either the exact sequences experienced during training or a general rule between initial and final words that could be applied to novel stimuli. A waking interval stabilized memory for the trained information, but did not produce generalization to new stimuli, whereas after sleep, infants could recognize novel stimuli that followed the same pattern (Gomez, R. L. *et al.*, 2006). When sleep was delayed, the generalization to new stimuli did not occur (Hupbach, A. *et al.*, submitted). Infant memory may be too unstable to benefit except from immediate consolidation during sleep, which implies an adaptive value to the considerable sleep that infants engage in.

3.51.2.3 Multiple Processes of Memory Consolidation in Humans

These data indicate that human auditory memory is subject to several different forms of consolidation or offline processing. Evidence for offline processing is manifest most often after sleep but also occurs during the wake state. This processing serves to stabilize, enhance, or even restore memory that could not be demonstrated after a waking interval. It is unclear whether the variety of consolidation effects results from differences in tasks or because the tasks involve different neuronal systems. The most consistent pattern of consolidation entails memory stabilization during a waking interval and memory enhancement after sleep. This pattern is found in rote motor and auditory memory and declarative memory for associated word pairs but is somewhat different in a visual rote memory task where fatigue plays a factor.

For generalized learning, a distinct pattern of consolidation emerges. A generalized sensorimotor task and a generalized spoken language learning task show both that a waking interval degrades performance from initial performance gains but that a subsequent sleep period restores memory that was inaccessible and that sleep inoculates the memory against waking degradation. Thus, within the class of nondeclarative learning tasks, the pattern of consolidation for generalized learning differs markedly from consolidation effects found acquiring simpler nondeclarative skills. We hypothesize that complex generalized skills recruit a broader network of cortical and subcortical structures than do simple skills, and sleep-dependent learning of complex generalized skills involves interaction between a diverse set of brain regions. This latter theme is taken up next as we consider animal studies.

3.51.3 Sleep and Memory Consolidation in Animals

Sleep and memory consolidation has been studied more in humans than in animals. There is still no paradigm comparing simple skill with generalized learning in adult animals. Laboratory studies directed toward neurophysiological investigation of sleep and learning have focused on naturalistic behavior (Dave, A. S. and Margoliash, D., 2000; Poe, G. R. *et al.*, 2000; Frank, M. G. *et al.*, 2001).

3.51.3.1 Bird Song Learning

The study of bird song learning takes advantage of attributes of the auditory modality for naturalistic studies. The behavioral context of species-specific vocalizations can give insights into the potential significance of neuronal stimulus selectivity (Margoliash, D. and Konishi, M., 1985) and vocal behavior is amenable to study, in that the auditory signal itself is the referent both for production and for perception

(Marler, P., 1970a; Tchernichovski, O. *et al.*, 2001). Furthermore, for sleep research, audition has advantage over vision, in that natural stimuli can be presented without special consideration during sleep (Dave, A. S. *et al.*, 1998).

Birdsong also shares deep similarities with speech and language acquisition in humans (Marler, P., 1970b; Doupe, A. J. and Kuhl, P. K., 1999), which extends to the role of sleep in vocal learning (Margoliash, D., 2003). Typically, true songbirds (oscine passerine birds, hereafter songbird) become sensitive to exposure to adult male songs at approximately the time they fledge, with the duration of this sensory phase being highly variable across species and environmentally sensitive (Kroodsma, D. E. and Pickert, R., 1980). The song memories formed during this phase have been described as an acquired sensory template that guides subsequent sensorimotor learning. Sensorimotor interactions are implicated in song learning, in that auditory feedback is necessary for normal vocal development (Konishi, M., 1985) and, for some species, also for adult song maintenance (Nottebohm, F. *et al.*, 1976; Nordeen, K. W. and Nordeen, E. J., 1992; Okanoya, K. and Yamaguchi, A., 1997; Leonardo, A. and Konishi, M., 1999). Furthermore, although audition is the principal medium that guides song learning, social interactions can moderate (Payne, R. B., 1983; Baptista, L. F. and Petrinovich, L., 1986) and in some special cases even directly guide song acquisition (West, M. J. and King, A. P., 1988). Thus, the separate but linked processes of perception and production in birds mimic the basic features of ontogeny of human speech and language. There are *c.* 3500 species of oscine birds that exhibit a broad variety of learning and singing strategies but no primate species other than humans with highly plastic vocal behavior. Passerines therefore represent a treasure trove of biological richness whose exploration has barely begun.

3.51.3.2 The Role of Sleep in Song Learning: Circadian Deconsolidation during Vocal Development

In the long history of research in birdsong learning, the potential of sleep to influence the learning process has only recently been considered (Margoliash, D., 2002). In the traditional instructional model, the environment directly guides song development (Konishi, M. 1965; 1978). In a proposed selectional model, the environment biases choices of innately specified sensory or motor patterns (Marler, P., 1998). In both cases, feedback has been envisioned as acting directly and immediately, either being compared with the template or enhancing matching internal representations. In such systems, the memory required for the feedback signal is short, perhaps only long enough to resolve the temporal credit assignment problem (Sutton, R. S. and Barto, A. G., 1998) – the delay between when neuronal commands are formed and feedback from the resulting gestures return to the brain.

Recent behavioral results have challenged this perspective. Analysis of song variability throughout ontogeny has demonstrated that vocal development of zebra finches shows a strong sleep-dependent effect (Deregnaucourt, S. *et al.*, 2005). Sleep acts to deteriorate song production in juveniles, which is then reversed by subsequent daytime singing, a process that has been termed deconsolidation. Syllable production before and after sleep shows greater variation than when compared during the morning and afternoon (Figure 2). Importantly, individual variation in the magnitude of the fluctuations predicts the degree of learning. Birds with the largest fluctuations are those that ultimately produce the most faithful copies of the tutor songs (Deregnaucourt, S. *et al.*, 2005). Deconsolidation is related to sleep itself and is dissociated from a purely circadian effect. For example, a similar pattern is also observed when

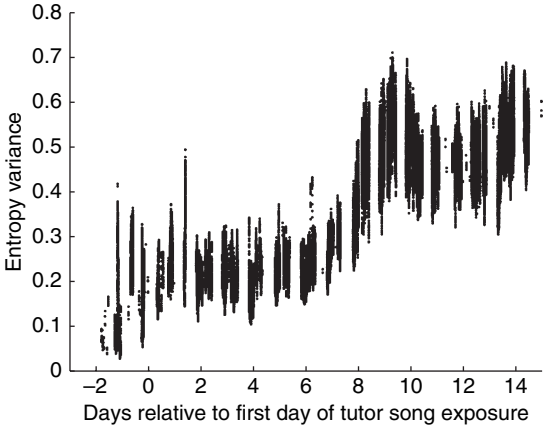

Figure 2 Analysis of song development. An example of the circadian variation in the entropy variance for one cluster (roughly representing one or more syllables) from 2 days prior to the first day of tutoring to 14 days after tutoring onset. The magnitude of the circadian variation increases following the onset of tutoring. This analysis was performed using the Song Analysis software (Tchernichovski, O. *et al.*, 2001).

sleep is artificially induced. Birds that are housed in the laboratory in the morning and precluded from experiencing intense singing until the afternoon also show the same pattern. Furthermore, juveniles raised in isolation from tutor songs show little variation in singing after sleep.

Humans and some bird species including zebra finches also rely on auditory feedback to maintain adult vocalizations. Modifying feedback in adult birds, either by deafening (Nordeen, K. W. and Nordeen, E. J., 1992) or via a syllable-triggered delay procedure during production (Leonardo, A. and Konishi, M., 1999), causes song degradation. Adult song maintenance has been used as a surrogate for song development, under the assumption that similar plastic mechanisms are involved. Small circadian fluctuations in adult singing occur over short periods of time and throughout the day (Chi, Z. and Margoliash, D., 2001; Glaze, C. M. and Troyer, T. W., 2006). A role of sleep in these circadian fluctuations, or during song degradation, has yet to be reported.

3.51.3.3 Implications of Circadian Deconsolidation for Models of Song Learning

A heuristic for evaluating deconsolidation during song learning comes from consideration of artificial neural networks. In a high-dimensional space, an effective search algorithm is to add energy to the system, thereby escaping from local minima. Slowly cooling the system (reducing energy) helps to achieve stabilization at a better (lower energy) solution. Adding too little energy constrains the search space, which could result in poorer learning. This heuristic views sleep as performing a random search of the space of solutions (Deregnaucourt, S. *et al.*, 2005). Below, we suggest an alternate hypothesis.

Because the quality of juvenile song is regulated in part by a mechanism expressed during sleep, this could suggest that the effects of sleep are related to motor processing (a nondeclarative task). An alternate hypothesis is that the acquired sensory template for song learning is itself modified on a circadian basis. The copy accuracy of the template may degrade each night because of passage of time without reinforcement. This hypothesis, however, is hard to reconcile with the observations that song learning can proceed with only minimal exposure to tutor songs. Isolated zebra finches learn best when only exposed to approximately 20 songs per day throughout the developmental period (Tchernichovski, O. *et al.*, 1999), and in European nightingales, just a few days exposure to tutor songs can result in veridical song learning (Hultsch, H. and Todt, D., 1989). Alternatively, auditory feedback could be modifying the sensory template during the day, and the effects on the sensory template could be expressed in nighttime activity. Notably, this implies that activity during sleep is better described by a directed, not random, search. The language abstraction results in human infants (Gomez, R. L. *et al.*, 2006), and the prior results showing sleep effects on speech perceptual learning (Fenn, K. M. *et al.*, 2003) help to emphasize the point that sleep may be acting in concert with sensory structures.

3.51.4 Mechanisms of Sleep and Memory Consolidation in Humans

We now turn to the neuronal mechanisms that might be associated with memory consolidation during sleep, first considering the data for humans. The diverse set of behavioral results in humans indicates that the consolidation process may differ across types of memory (e.g., declarative vs. nondeclarative) or forms of learning (e.g., rote vs. generalized). In recent years, neuroimaging experiments have yielded insight into the mechanisms underlying these processes.

3.51.4.1 Evidence for Reactivation during Sleep in Humans

Neuroimaging techniques used in a range of human studies have observed changes in brain activation both during and after a period of sleep. One central observation is that brain regions active during a task can be reactivated during sleep (Maquet, P. *et al.*, 2000; Peigneux, P. *et al.*, 2004). Hippocampal activity elicited during a virtual spatial navigation task is replayed during subsequent SWS, and activation in task-related areas in a serial reaction time task (SRT) is replayed during REM sleep (Maquet, P. *et al.*, 2000). Furthermore, the amount of reactivation in spatial learning in humans is positively correlated with performance (Peigneux, P. *et al.*, 2004). Whether the difference in sleep stage-specific effects of reactivation is related to different mechanisms of consolidation remains unresolved. Of course, it is important to note that reactivation in humans refers to localized changes in brain activity, whereas

reactivation in experimental animals is defined by examining spatial/temporal patterns of activity in individual neurons or populations of neurons.

3.51.4.2 Changes in Cortical Representations of Memory After Sleep

In humans, replay acts as a form of offline practice of information. Similar to waking practice, as the amount of offline practice increases, performance benefits also increase. Offline processing could act to simply strengthen the patterns of connections (memory representations) established during the initial learning phase. In addition, offline processing could act to change those patterns of connections, changing the way the memory is represented or accessed. While there are no studies that have looked both at reactivation during sleep and subsequent neural processing of the same information in humans, the behavioral evidence suggests that sleep strengthens the cortical representations of a memory and also changes the functional connectivity of the memory.

In skill learning, sleep has been found to produce an expansion of the cortical representation of the memory in primary sensory or motor cortices and also to change the functional connectivity in subcortical and higher-level cortical areas (Walker, M. P. *et al*., 2005a; 2005b). These changes are first observed after a period of sleep and are not produced after a waking interval. However, they persist and continue to evolve over a period of several days or weeks, and perhaps longer (Karni, A. *et al*., 1995; Pascual-Leone, A. *et al*., 1995). The neural plastic changes are associated with behavioral plasticity; performance after a period of sleep is significantly better than after a waking interval.

Neurophysiological changes resulting from consolidation are found not only in the quantity of neural activity elicited by a task but also in qualitative changes in event-related potentials (ERPs). Behavioral improvement in an auditory discrimination task continues for at least 48 h after training and changes in various ERP components also evolve over this time course, in the absence of additional task exposure (Atienza, M. *et al*., 2002). In particular, the amplitude of the mismatch negativity (MMN), which is thought to underlie automatic detection of an auditory change, is significantly enhanced 36 h after training. This is accompanied by a decrease in reaction time and similar to the effects found in functional neuroimaging; the amplitude of the MMN was found to be strongly, though insignificantly, correlated with reaction time.

3.51.4.3 Slow Wave Activity Effects on Consolidation

Reactivation and changes in cortical representations interact with the backdrop of transitions through sleep stages during consolidated sleep in humans. These interactions are integral to the consolidation process. For example, it has been proposed that SWS is important to memory consolidation and that the slow oscillating waves may reflect the transfer of information from the hippocampus to the neocortex (Buzsaki, G., 1998). Recently, it was found that boosting these oscillations via transcranial stimulation enhances declarative memory. The amount of memory enhancement exceeds that found after normal, undisturbed, SWS (Marshall, L. *et al*., 2006). This is particularly strong evidence to suggest that synchronous activation of populations of neurons as reflected in slow wave activity (SWA) plays a causal role in declarative, hippocampal-dependent memory.

Substantively altering electroencephalography (EEG) patterns during SWS is one approach to unraveling the effect of SWS on memory, but if SWA is indeed important for consolidation, it follows that the formation of a memory may alter patterns of SWA in subsequent sleep, reflective of consolidation. Indeed, after learning a motor adaptation task, localized increases in the amount of SWA are found in parietal cortices (Huber, R. *et al*., 2004) implicated during waking task performance. The increase in SWA is not found globally over all of cortex but is restricted to task-related areas. Moreover, the amount of SWA during sleep is correlated with subsequent performance. This lends additional support to the existence of a link between SWA and memory consolidation.

3.51.5 Mechanisms of Sleep and Memory Consolidation in Vocal Learning

The two principle animal neurophysiological models of sleep effects on learning have focused on naturalistic behaviors – spatial navigation by rats and vocal learning by songbirds. The former is considered a form of declarative memory and the latter a form of nondeclarative memory, but each behavior may have elements of both. For example, a rat may have an internal map of extrapersonal space and follow a procedure (path) to a target, and a songbird (especially one with a multiple song repertoire) may have labels attached to each song type. In both cases, the

associated learning mechanisms are complex and require integration across multiple modalities. Here we focus on vocal learning in songbirds. The results from nondeclarative learning experiments in humans would predict that sleep would have a significant, and complex, interaction with vocal learning.

3.51.5.1 Auditory Pathways Leading to the Song System

An extensive set of pathways that contribute to song learning have been elucidated over the past 30 years (Figure 3). Principally, these include a forebrain ascending auditory pathway, a forebrain descending vocal motor pathway, an ascending brainstem vocal-respiratory pathway, and an anterior forebrain pathway which forms a separate major loop connecting nuclei of the descending vocal motor pathway. Neuromodulatory inputs to the song system have also been identified. The modern reinterpretation of the avian forebrain as being mostly pallial has facilitated our understanding of the song learning pathways (Reiner, A. *et al.*, 2004). The organization of the avian forebrain has been related to mammalian cortical organization, including elements of the auditory pathway and descending motor pathway (Karten, H. J., 1997). The anterior forebrain pathway has homology with the corticobasal ganglia pathway in mammals. The neuromodulatory systems of birds and mammals are apparently homologous.

In the forebrain, the ascending auditory pathways include a thalamorecipient Field L (Karten, H., 1968), and its projections to secondary auditory areas including the caudal medial nidopallium (NCM) and the caudal mesopallium (CM). NCM projects to the caudomedial mesopallium (CMM) and CMM projects to the caudolateral mesopallium (CLM). Most connections within Field L and between areas are unilateral and reciprocal (Mello, C. V. *et al.*, 1998). In many ways, the organization of these pathways resembles that for mammalian auditory forebrain (Kass, this volume). CLM projects to the nucleus interface of the nidopallium (NIf) (Mello, C. V. *et al.*, 1998). Physiological observations indicate that this pathway may serve as the principal auditory input to the song system (Janata, P. and Margoliash, D., 1999; Coleman, M. J. and Mooney, R., 2004).

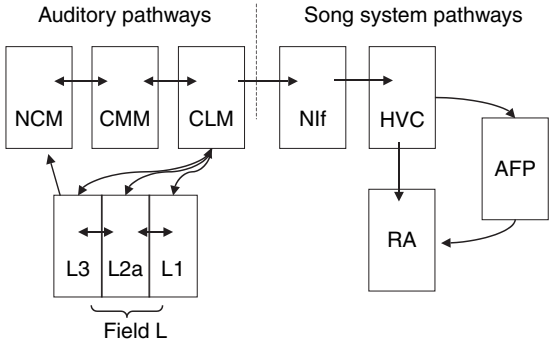

Figure 3 A highly simplified representation of the forebrain auditory and song system pathways in songbirds. Field L receives thalamic input. Auditory input to the song system arises through the projection of CLM to NIf. RA is the principal forebrain output of the song system. The AFP comprises three nuclei (not shown). Auditory responses are found in all the song system nuclei but are distinguished from auditory pathway nuclei by the selective responses to the bird's own song.

3.51.5.1.1 Physiological specificity within the auditory pathways

The hierarchical anatomical relations of the forebrain auditory pathways correlate with a number of physiological properties of these pathways. Neurons in the granular layer L2a in Field L have simple response properties. They typically respond vigorously to tone bursts and often to broadband noise bursts and have a narrow range of frequencies that elicit excitation often with inhibitory frequency surrounds. Within field L, tonotopic organization is most robust in L2a.

In contrast, neurons in the surrounding L1 and L3 regions of Field L have more complex response properties. L1 and L3 neurons often respond less vigorously or not at all to tone bursts. A greater number of L1 and L3 neurons respond more selectively to a repertoire of species-specific and other complex natural vocalizations, and responses for some neurons are based on multiple spectral features of species-specific vocalizations (Leppelsack, H.-J. and Vogt, M., 1976; Bonke, D. *et al.*, 1979).

Neurons in the secondary auditory nuclei can have particularly complex and selective responses. For example, many neurons in the starling CMM respond highly selectively when presented a repertoire of songs (Stripling, R. *et al.*, 1997; Gentner, T. Q. and Margoliash, D., 2003; Terleph, T. A. *et al.*, 2006). Quantitative analysis of input–output transfer functions of single neurons also supports these conclusions, showing a hierarchical relation comparing L2a with other Field L subdivisions and CM (Sen, K. *et al.*, 2001; Theunissen, F. E. *et al.*, 2004).

3.51.5.1.2 Behavioral and neural plasticity in the auditory pathways

Studies of adult animals using a variety of techniques indicate that the secondary auditory areas express plasticity throughout life that could contribute to memory formation. A remarkable form of plasticity has been described with gene expression studies. The immediate early gene (IEG) *zenk* shows a complex pattern of expression in NCM and CM in response to auditory stimulation (Mello, C. V. *et al.*, 1992; Mello, C. V. and Clayton, D. F., 1994; Terpstra, N. J. *et al.*, 2005). This includes sensitivity to acoustic features of conspecific songs, heightened response to conspecific vs. heterospecific songs, and lack of expression to simple stimuli such as tone bursts. If the same conspecific song is presented multiple times, *zenk* expression drops and remains at suppressed levels until the bird is presented with a novel song (Chew, S. J. *et al.*, 1995; Mello, C. *et al.*, 1995). Single and multicell recordings also demonstrate some evidence of habituation (Stripling, R. *et al.*, 1997; Gentner, T. Q. and Margoliash, D., 2003; Terleph, T. A. *et al.*, 2006), although the relation between *zenk* and electrophysiological habituation is complex.

In adult starlings trained on an operant song recognition task, the population of CMM neurons as assessed by sequential, single-cell recordings was found to be biased toward the songs birds had learned to discriminate (Gentner, T. Q. and Margoliash, D., 2003). A large proportion of the neurons exhibited strong, selective responses to one or a limited number of songs and much weaker responses to unfamiliar songs. The strength of response was related not only to familiarity but also to behavioral valence: in a Go-Nogo paradigm, neurons exhibited much stronger responses to the Go stimulus than to the Nogo stimulus, but stronger responses to the Nogo stimulus than to unfamiliar songs. Thus, both IEG expression studies and extracellular recordings indicate that secondary auditory pathways participate in the formation of long-term memories in adult animals.

The conspecific songs birds commit to memory early in life drive vocal learning. IEG expression studies have examined tutor song representations, searching for long-term memory for tutor songs in adult zebra finches. Exposure of adult males to song they were tutored with as juveniles elicited expression of *zenk* and *c-fos* (Bolhuis, J. J. *et al.*, 2000). In female zebra finches, levels of Zenk protein product in CMM were significantly higher when birds were re-exposed as adults to their tutor songs than when exposed to novel songs (Terpstra, N. J. *et al.*, 2006). This design removes the confound that males engage in self-stimulation with a close copy of the tutor song when they sing, because female zebra finches do not sing. These results are also supported by multiunit studies of habituation in NCM, which show greater (and significant) habituation in adults exposed to tutor songs than in adults exposed to unfamiliar songs, and a correlation between the degree of habituation and the degree of song copying (Phan, M. L. *et al.*, 2006). When tested with playback of the bird's own song (BOS), the correlation with habituation strength is not observed. This implies that the observed correlations do not result from similarity between tutor and own songs.

In summary, converging data from behavior, electrophysiological, and gene expression studies indicate that secondary auditory areas in songbirds exhibit plasticity throughout life, with some populations of single neurons exhibiting selective responses to learned, behaviorally relevant stimuli. The effect of behavioral state has been extensively examined from the perspective of the strong habituation to familiar songs observed in gene expression and neuronal activity. The habituation phenomenon may focus attention on new songs, and attendant neural plasticity may elicit rapid representational reorganization, allowing songbirds to acquire and perhaps retain multiple song memories throughout life. In young birds in the process of acquiring songs, these memories could represent a component of the long-hypothesized template for birdsong learning. The impact of the conclusions regarding developmental mechanisms is tempered by the principal limitation that relatively few observations have been made in juvenile birds (Jin, H. and Clayton, D. F., 1997; Stripling, R. *et al.*, 2001; Bailey, D. J. and Wade, J., 2003; 2005). This identifies a path for future research.

3.51.5.2 State-Dependent Auditory Processing in the Song System of Awake Birds

In the songbird forebrain, auditory responses are expressed extensively throughout the song system, with numerous properties reflecting the sensorimotor nature of singing. In adult birds, song system neurons exhibit strong preference for playback of BOS (Margoliash, D. and Konishi, M., 1985; Doupe, A. J., 1997). In zebra finches, with a single song repertoire, the response to song playback shows a consistent pattern of complex temporal dynamics throughout HVC (Sutter, M. L. and Margoliash, D., 1994),

which is also seen in other song system nuclei. In song sparrows, with a multiple song repertoire, there is more local variability in response to song playback (Nealen, P. M. and Schmidt, M. F., 2006). Auditory responses of HVC neurons are exquisitely tuned to features of BOS (Margoliash, D., 1983; Theunissen, F. E. and Doupe, A. J., 1998), including sensitivity to temporal sequences of song syllables (Margoliash, D., 1983; Doupe, A. J., 1997). The structuring of auditory responses in the song system by features of BOS differentiates auditory responses in the forebrain auditory pathways from those in the song system and emphasizes the role of auditory feedback in song learning and maintenance.

The auditory responses of song system neurons are also strongly modulated by behavioral state, with large differences observed across species. Early studies using chronic multiunit recordings in awake canaries and white-crowned sparrows observed robust HVC auditory responses (McCasland, J. S. and Konishi, M., 1981; Margoliash, D., 1986), which has also been confirmed in the HVC of song sparrows (Nealen, P. M. and Schmidt, M. F., 2006). In contrast, auditory responses in the song system including HVC are suppressed in awake zebra finches (Dave, A. S. *et al.*, 1998; Schmidt, M. F. and Konishi, M., 1998) but in a complex pattern involving some but not all classes of HVC neurons (Rauske, P. L. *et al.*, 2003). Responses in awake white-crowned sparrows varied according to behavioral state such that weaker responses and loss of bursting activity were observed just prior to periods of arousal, although this was observed anecdotally (Margoliash, D., 1986). In a controlled study, the responses of HVC in zebra finches showed similar properties, with stable, BOS selective responses in sedated birds and far more variable, arousal-dependent, and less BOS selective responses in awake birds (Cardin, J. A. and Schmidt, M. F., 2003). The species differences in song system auditory responses in awake birds might reflect ecological aspects of social organization, such as comparing territorial and gregarious species, but this remains speculative.

3.51.5.2.1 Neuromodulatory processing in the song system of awake birds

Both cholinergic and adrenergic systems have been implicated in state-dependent processing in the song system. In birds, as in mammals, neuromodulatory systems access forebrain neurons, and there is varying and in some cases substantial evidence of cholinergic and adrenergic input to nucleus uvaeformis (Uva), NIf, HVC, and RA. HVC is the principal source of auditory input to robust nucleus of archopallium (RA) and to the anterior forebrain pathway (Doupe A. J. and Konishi, M., 1991). Injection of cholinergic agonists and antagonists into HVC, and in the presence of stimulation of the cholinergic basal forebrain, indicates strong cholinergic regulation at the level of HVC, with different classes of cholinergic receptors regulating auditory output to RA and to the anterior forebrain pathway (Shea, S. D. and Margoliash, D., 2003). This may give rise to differential expression of auditory activity in the forebrain song system, with complete suppression of auditory responses in RA (Dave, A. S. *et al.*, 1998) but not in the anterior forebrain pathway. Lesioning the cholinergic basal forebrain results in rapid song deterioration, in some cases followed by substantial recovery of song structure (Levin, T. *et al.*, 2005). NIf neurons may be the first in the song system to show selectivity for BOS and may give rise to the principal source of auditory input to the song system (Janata, P. and Margoliash, D., 1999; Coleman, M. J. and Mooney, R., 2004; Cardin, J. A. *et al.*, 2005). Auditory activity in NIf is strongly regulated by noradrenergic mechanisms (Cardin, J. A. and Schmidt, M. F., 2004), as is auditory activity in HVC (Dave, A. S. *et al.*, 1998). Uva, which has been implicated in regulating singing (Coleman, M. J. and Vu, E. T., 2005), receives cholinergic input from the habenula (Akutagawa, E. and Konishi, M., 2005).

Collectively, these data imply that cholinergic and noradrenergic systems have powerful influence on sensory activity in the song system and that the cholinergic system has powerful influence on singing behavior. Neuromodulatory input to Uva and HVC might be recruited to release song pattern generators. Neuromodulatory systems could also act to regulate auditory input to the song system. In awake quiescent birds, this could help regulate the flow of auditory information to the anterior forebrain pathway, which has been implicated in song recognition behavior (Brenowitz, E. A., 1991; Burt, J. M. *et al.*, 2000). In singing birds, this could help regulate the flow of auditory feedback to the anterior forebrain pathway (AFP) and the descending motor system. In developing birds, neuromodulatory systems might help focus attention on the songs of potential adult tutors. Finally, these same neuromodulatory mechanisms could have particularly profound effects during sleep, when the functional properties of the song system are dramatically altered. This possibility is considered in the next section.

3.51.5.3 Replay and Plasticity during Sleep

As an adult bird begins to sing, RA neurons transition from a highly regular spontaneous tonic firing mode to a bursting firing mode superimposed over complete inhibition of spontaneous activity. The tonic firing mode is characterized by single mode, Gaussian-shaped inter-spike interval (ISI) histograms (Figure 4(a)). The bursting firing mode is characterized by individual spike bursts that are exceptionally reliable and well structured (Yu, A. C. and Margoliash, D., 1996). Combined, this results in a bimodal ISI distribution. In virtually all cases, each burst of spikes can be assigned a unique identity, with a typical neuron emitting circa 20 different burst types during a motif of song (Figure 5). The dictionary is unique for each neuron, that is, the timing and structure of a given burst cannot be predicted for a given neuron, but knowing that dictionary one can reliably read off the singing behavior just by examining the activity pattern of a single RA neuron (Yu, A. C. and Margoliash, D., 1996). Converging feed-forward excitation from sparse-firing, HVC-RAn has been posited as dominating the firing properties of RA neurons (Leonardo, A. and Fee, M. S., 2005).

3.51.5.3.1 Site and form of the replay phenomenon

During sleep, state transitions are observed that mimic those associated with daytime singing (Dave, A. S. *et al*., 1998; Dave, A. S. and Margoliash, D., 2000). ISI histograms obtained during sleep are bimodal. A short-duration ISI mode (corresponding to bursting) has a similar structure to that obtained for singing. The peak may be shifted toward longer ISIs, reflecting the higher-frequency bursting obtained during singing than during sleep, and the shape of the short-duration ISI mode reflects the greater variability in bursting observed during singing. A long-duration ISI mode may be anisotropic, corresponding to the combination of regular firing mode activity with long inter-burst intervals from the bursting firing mode activity. The peak of the long-duration ISI mode is also shifted toward longer ISIs, reflecting slower spontaneous activity during sleep than in awake birds. ISIs obtained from anesthetized birds are similar to those obtained during sleep (Figure 4(b)).

The similarity of the short-duration ISI mode obtained from RA neurons in singing and sleeping birds results from bursts emitted during sleep that have similar patterns to those bursts emitted during singing (Dave, A. S. and Margoliash, D., 2000). This

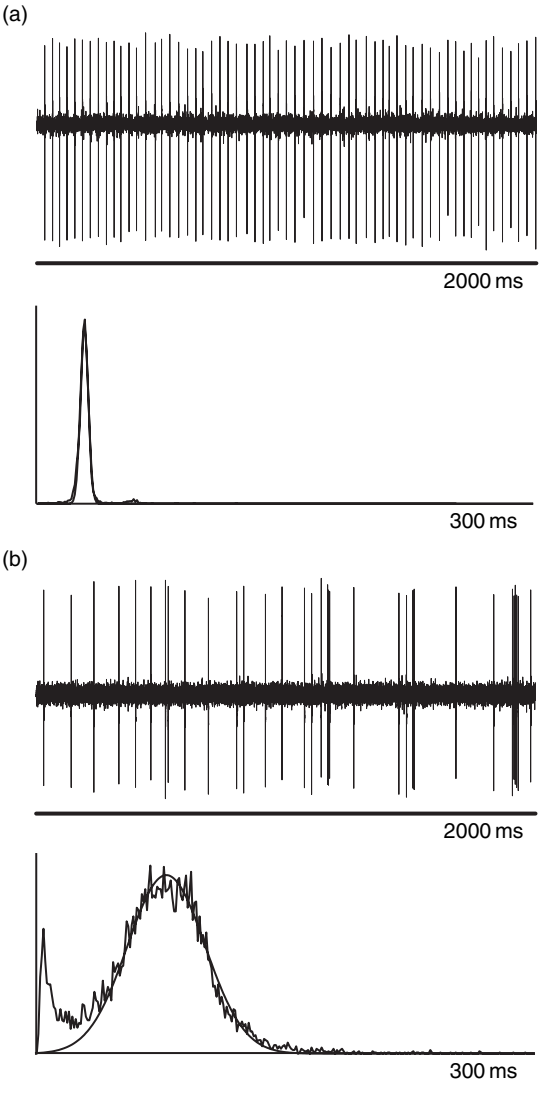

Figure 4 Spontaneous discharge in RA neurons in an awake quiescent bird (a) and in a urethane anesthetized bird (b). In each part, the top panel shows a raw record and the bottom panel shows an ISI histogram fitted with a Gaussian. The fit is excellent for (a) but only for the long-duration ISI peak in (b), because in anesthetized (and sleeping) birds, there are short ISIs associated with bursting.

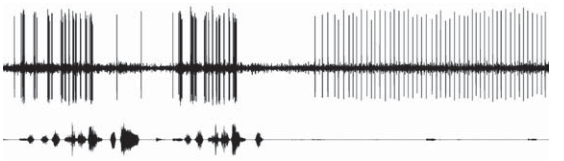

Figure 5 Activity of RA neuron (top trace) during singing (oscillograph, bottom trace); traces are 5 s in duration. Note the bursting activity and recovery of regular firing pattern after postsong inhibition.

represents a replay (reactivation) phenomenon, one that is observed at the level of single cells. In comparison, reactivation in the hippocampus is related to ensemble patterns (Wilson, M. A. and McNaughton, B. L., 1994; Skaggs, W. E. and McNaughton, B. L., 1996). In the zebra finch, comparing only on a burst-by-burst basis, only approximately 15% of bursts show a statistically significant match. This number is likely to be an underestimate because it fails to consider sequences of bursts that are also observed during sleep. Nevertheless, it is important to emphasize that many bursts during sleep may not match or may only poorly match the structure of bursting during singing. This implies that variability exists during sleep that could be the substrate for plasticity.

The replay phenomena as described above relies on comparison of bursting activity during singing and during spontaneous sleep in the same neurons, which is a technically difficult experiment. By this definition of replay, replay in the song system has been confirmed only for RA neurons. However, several structures show similar firing properties in both wake and sleep. Neuronal activity in HVC of sleeping birds shares similarities with activity observed in awake birds, with RA-projecting HVC neurons (HVC-RAn) and Area X-projecting HVC neurons (HVC-Xn) exhibiting sparse firing and interneurons exhibiting tonic firing (Hahnloser, R. H. *et al.*, 2002; Rauske, P. L. *et al.*, 2003). In sleeping birds, NIf neurons show bursts that are correlated with HVC bursts, and silencing NIf stops HVC sleep bursting (Hahnloser, R. H. and Fee, M. S., 2007). The overall levels of NIf activity are higher in fully awake than lightly sedated birds (Cardin, J. A. and Schmidt, M. F., 2004), but bursting statistics are not altered in sleeping birds (Hahnloser, R. H. and Fee, M. S., 2007). Overall burst rates are similar in RA-projecting LMAN neurons (LMAN-RAn) in sleeping zebra finches (Hahnloser, R. H. *et al.*, 2006), but during singing, bursts in LMAN are not time-locked to song syllables (though some spikes are) (Leonardo, A. 2004).

Collectively, these data suggest that replay is limited to the descending motor pathway, but for HVC (and possibly Uva), the existence of replay has yet to be directly confirmed. Whereas analysis of bursting in sleeping birds can give insight into the mechanisms generating bursting, the fidelity of replay – variability of bursting during sleep as compared to bursting during singing – has yet to be assessed. If variability of activity during sleep is important for plastic mechanisms during sleep, as we argue below, this attribute will be important problem to address in future work. The other implication is that replay will be particularly difficult to assess in juvenile birds, because song is plastic (variable) as are the bursting properties of song system neurons. This implies the need to acquire a larger data set to achieve statistical significance comparing singing and sleeping bursting, a challenging task.

3.51.5.3.2 Plasticity in Robust Nucleus of Archopallium replay – spontaneous and auditory activity

The replay phenomenon exhibited by RA neurons opens the possibility that neuronal activity patterns change during sleep and that these changes are part of a plasticity mechanism associated with song learning in juvenile birds and song maintenance in adult birds. The exceptional precision of RA bursting during singing in zebra finches was exploited to search for such adaptive changes. Single neuron recordings commenced while the animal sang near the end of its normal diurnal phase and continued through a period of sleep and a bout of singing immediately upon wakening. A principal observation was that consistent if subtle changes in the patterns of spike bursting were observed comparing activity during singing before and after a period of sleep (Rauske, P. L. *et al.*, 2001). Such changes also were observed during daytime singing, but at a much lower frequency of occurrence. In this small data set, it was difficult to associate the neuronal changes directly with behavioral vocal plasticity. Nevertheless, these observations establish that long-term changes in the structure of neuronal bursting can be mediated via changes occurring during sleep.

As well as changes in spontaneous discharge properties, during sleep, song system neurons acquire heightened sensory responses (Dave, A. S. *et al.*, 1998; Dave, A. S. and Margoliash, D., 2000; Cardin, J. A. and Schmidt, M. F., 2003; Rauske, P. L. *et al.*, 2003). The most dramatic changes observed to date are for zebra finch forebrain RA neurons, which exhibit vigorous responses to BOS playback during sleep and no response while awake. A systematic analysis of the degree of variation in BOS playback that RA neurons will tolerate during sleep has yet to be reported, but the neurons exhibit high selectivity of response. In general, conspecific songs elicit no response or inhibition, compared to exceptionally robust responses to BOS.

The structure of the response to playback during sleep shows visually compelling and statistically significant similarity to the structure of activity of the same neurons during daytime singing (Figure 6). This is observed comparing both the timing and the

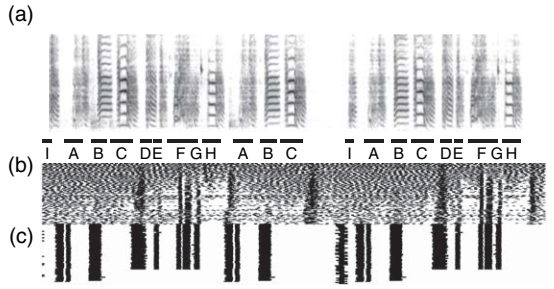

Figure 6 Activity of a single RA neuron in relation to song shown in (a); (b) response of the neuron to song playback while the bird sleeps; (c) premotor activity of the same neuron while the bird is singing (b) and while it is listening (auditory response) to playback of its own song auditory response (c) in relation to the song (a). The letters under the spectrograph in (a) identify syllables that are repeated multiple times in the song.

structure of individual bursts emitted during BOS playback and during singing, although there tend to be fewer spikes in the bursts stimulated by BOS. It is common, however, that neurons participate throughout more of song during singing than they do when stimulated by BOS playback during sleep so that neurons exhibit ongoing discharge to some syllables of BOS playback (Figure 6). Furthermore, during singing RA neurons are premotor, their discharge leads and predicts the notes and syllables that will follow. During BOS playback, nonlinear integration over preceding syllables releases RA responses.

Thus, there are similarities to the structure of spike bursts spontaneously emitted during sleep, or spike bursts emitted during song playback, as compared with spike bursts emitted during singing. Nevertheless, the patterns of activity are not the same. The variability in the structure and timing of spontaneous bursting during sleep could serve to drive sleep-induced changes, which is predicted by the song developmental studies. The upregulation during sleep of auditory activity in the descending motor system suggests the possibility that the system enters a plastic state, where memories of auditory feedback can drive changes in premotor networks.

3.51.5.3.3 Sleep-mediated developmental plasticity in Robust Nucleus of Archopallium

Virtually, all the data acquired with regard to replay have been collected in adult birds or in late juvenile birds (Dave, A. S. and Margoliash, D., 2000; Kozhevnikov, A. and Fee, M. S., 2007). In a recent study, the spontaneous activity of RA neurons was examined in sleeping juvenile birds in the nights before and after the birds first gained access to tutor songs at circa 42 days of age (Shank, S. and Margoliash, D., 2006). Prior to being exposed to a tutor song, RA neurons exhibited little spontaneous bursting, and ISI histograms had a unimodal peak centered at long intervals. A dramatic change was observed starting the night of the first day the birds were exposed to tutor songs. RA neurons exhibited greatly increased spontaneous bursting. ISI histograms had bimodal peaks, with the second peak centered at short intervals. In contrast, the number of spontaneously emitted bursts in RA normally emerges slowly during development (Adret, P. and Margoliash, D., 2002). The sudden emergence of bursting correlated with the first days of tutoring, however, demonstrates that tutoring strongly influences the structure of sleep activity in the descending motor system. Furthermore, the structure of the ISIs was dependent on which tutor song the birds were exposed to. Thus, the effects of tutoring are not nonspecific, but rather parameters of the tutor songs (as of yet unknown) are encoded in the nighttime spontaneous activity of RA neurons. This provides the strongest evidence to date linking auditory activity in the motor system for song and the sensory phase of song acquisition.

The data from juvenile RA support a new hypothesis regarding song learning. Activity at night is an active process reflecting auditory memories. The principle memory represented is that of the song tutor model. We assume that this memory representation of the song tutor model is modified during development by RA network properties acquired in relation to daytime singing. Thus, song development can be viewed as a circadian iterative process of bringing two types of representations into conjunction, auditory memories expressed at night and singing activity expressed during the day. Activity at night modifies the premotor network and affects singing the following day; activity during singing stores information in the form of auditory feedback. Song is most variable in the hours immediately after waking because the influence of the auditory memories (i.e., interactions between two disparate representations, for auditory memory and singing) is strongest in the morning and is largely – but not entirely – erased by the afternoon following hours of singing. The strength of the influence of auditory memory should be reflected in the depth of circadian song disruption, hence birds with greater circadian variation in song ultimately achieve better copies (Deregnaucourt, S. *et al.*, 2005). This formulation

differs from the suggestion that circadian song deterioration during development results from song replay during sleep unaccompanied by auditory feedback (Deregnaucourt, S. *et al.*, 2005). It shares at least superficial similarities with the wake–sleep algorithm (Hinton, G. E. *et al.*, 1995).

If two representations interact, then they must be expressed by different populations of interacting neurons or by the same population in different states. If the same RA (and other song system) neurons are active during singing, then where are auditory memories stored? Altering auditory feedback in adult (Nordeen, K. W. and Nordeen, E. J., 1992; Leonardo, A. and Konishi, M., 1999) or juvenile (Fukushima, M. and Margoliash, D., 2006) birds disrupts song, but clear effects emerge only after 2 or more weeks. To date, recordings from song system neurons during singing in altered feedback conditions have failed to identify an auditory component in the activity patterns (Leonardo, A. 2004; Kozhevnikov, A. and Fee, M. S., 2007). One possibility is that in zebra finches, the auditory feedback component is small so that the effect of feedback perturbation is expressed only over long intervals and the signal is hard to detect in electrophysiology. None of the experiments rule out the possibility that feedback changes the representation of auditory memories of song, stored for example in secondary auditory pathways, and in turn these memories drive changes at night in motor behavior. The analysis of neuronal replay during sleep has provided support for this hypothesis. Thus, in some sense, with regard to vocal behavior, zebra finches may be hearing themselves more at night than during the day.

3.51.6 Conclusions and Future Directions

Converging behavioral and neurophysiological evidence strongly suggests that during sleep, active processing of newly learned material changes the memory representation. This processing can change the functional connectivity of the memory. In several of the examples described here, endogenous oscillatory patterns produced during SWS have been shown to improve memory. The data further provide some support for the hypothesis that the nature of the consolidation process varies based on task or modality, approximating the behavioral evidence reviewed earlier in this chapter, but this remains speculative.

We have conjectured that the outcomes of memory consolidation are not only divided along traditional memory subsystems, such as declarative and nondeclarative memory. Behavioral outcomes of consolidation also differ for simple, rote memory tasks and complex, generalized memory. We conjecture that the neurophysiological mechanisms of consolidation are distinct for simple memory and complex memory and that reactivation recruits neural networks of different extents in simple and complex tasks. We assume that learning a complex task is associated with establishing a pattern of coordinated recruitment across a larger set of cortical structures than for simple learning. The distributed memory trace of the complex task would make it more vulnerable to unrelated daytime activity, whereas perhaps a more focal representation associated with a simple task would make it more vulnerable to similar daytime activity (i.e., interference effects). Since any given replay exemplar during sleep only approximates the corresponding waking activity, coordinated replay distributed across multiple cortical and subcortical regions would carry additional (mutual) information about the complex task. This model predicts the reciprocal patterns of interactions between sleep and task learning that have been observed for complex but not simple learning.

The data from the bird song system support and extend this model. Similar to hippocampal-dependent spatial learning in rats, vocal learning involves coordination across multiple systems not only during waking behavior but also during sleep. Sleep reactivation is often described as a random walk. The recent observation that spontaneous activity in the song system is influenced by song tutoring implies that this view of reactivation is incomplete because nighttime activity may be supervised or structured by tutor song representations and possibly auditory feedback during singing. The potential contribution of sleep as a mechanism to bring disparate motor and sensory representations into congruence during vocal development helps to highlight that sleep contribution to learning is not a unitary phenomenon. Rather, sleep can be recruited in a variety of ways in service of a broad range of task requirements.

4.01.1 Introduction

> Smells are surer than sounds and sights to make your heart-strings crack.
>
> Rudyard Kipling

It is difficult for humans, being the visually oriented creatures we are, to appreciate the fundamental importance of chemical sensitivity to life. The ability to detect and respond in an adaptive manner to chemical signals serves as the primary window to the sensory world for most species of animals. Chemical sensitivity is present even in the simplest of the extant life forms: bacteria, slime molds, and protozoans. Indeed, all living cells are irritable to chemicals. This predisposition of cells to be perturbed by chemicals led to the eventual evolution of specific receptor proteins to detect chemical signals and, ultimately, to specific chemosensory organs. The fundamental importance of chemical sensitivity to life and health was recognized by the award of the 2004 Nobel Prize in Physiology or Medicine to Drs. Linda Buck and Richard Axel for their pioneering discovery of olfactory receptor proteins and the understanding of olfactory organization these groundbreaking findings allowed.

Most of our detailed knowledge of chemical sensitivity comes from relatively few, but evolutionary distant species of animals that allow for phylogenetic comparison, including nematodes, insects, crustaceans, fish, frogs, mouse, and rat. Insights gained from rapid advances in molecular biology greatly facilitate this comparison, especially using the experimental model organisms *Caenorhabditis elegans*, *Drosophila*, zebrafish, and mice. Comparison across phylogenetically distant animals can be difficult, however. Even the most fundamental of distinctions such as that between smell and taste can blur when one considers, for example, that lobsters and fish have anatomically distinct olfactory systems that even sniff. Yet odors for these animals are sapid molecules in solution, not unlike

the context in which tastants activate vertebrate taste receptor cells. The distinction between smell and taste is further obscured by the presence of taste receptor cells in fish that respond to the same molecules as fish olfactory receptor cells and with greater sensitivity than the olfactory receptor cells. Comparison across animals as phylogenetically distant as nematodes, flies, fish, and mice inevitably requires caution when even basic terminology such as olfaction and taste can be called into question. At the same time, understanding the phylogeny of chemical sensitivity can produce important new insight into how we detect smells and tastes. From the two examples just mentioned, for example, we learn that the fundamental difference between smell and taste must be based on something other than the signaling medium, the nature of the ligands, and the threshold of sensitivity – the descriptors traditionally used to distinguish these two chemosensory modalities in terrestrial vertebrates. We are challenged to understand what really is unique about the chemosensory modality we call olfaction. In addition to comparative studies leading to new questions and insights into chemical sensitivity, animal models provide the opportunity to perform experiments designed to answer those questions.

In this chapter, we take a broad view, trying to look through species-dependent differences in an attempt to reveal broad principles of chemical sensitivity. We conclude that, even though the details differ between phylogenetically diverse animals, general principles of chemical signal detection are shared by most species. Citations throughout are only representative and are not intended to be exhaustive.

4.01.2 Chemical Signals

4.01.2.1 Nature of Chemical Signals

Animals use chemical stimuli to communicate in an amazingly diverse array of behavioral contexts, many of which are hard to appreciate because the action of chemosensory cues is often subtle and difficult for humans to even envision. Chemical stimuli emanating from other species of organisms, known collectively as allelochemics (Whittaker, R. H. and Feeny, P. P., 1971), control prey localization, homing, symbiotic associations, territorial marking, predator deterrence and avoidance, metamorphosis and growth, and pollination, to name just a few examples. Other chemical stimuli of conspecific origin, known collectively as pheromones (Shorey, H. H., 1976), act far beyond their now well-known role as sex attractants, a function which has been described in most animal phyla. For example, recognition pheromones denote the identity of individuals, social status, social group, and place; aggregation pheromones mediate feeding, sex, and aggression; dispersion pheromones maintain individual spacing and minimize predation; and reproductive pheromones trigger courtship displays and postures. In addition to these triggering functions, pheromones also serve priming functions in equally diverse contexts, in which the chemical stimulus additionally or alternately initiates longer term changes in the state of the recipient animal rather than just triggering immediate, overt responses (Vandenburg, J. G., 1983). The many, diverse behavioral roles chemical stimuli serve in phylogenetically diverse animals underscore the extreme importance of chemical sensitivity.

Many classes of molecules fall within the theoretical limits of molecular size and type for signal function, especially when one considers that these limits expand for chemical signals that can travel by bulk flow in aqueous media and that signals are not restricted to volatile molecules that can diffuse through air. The enormous information content inherent in having such a large number of potential signal molecules is one of the hallmarks of chemosensory communication. Given the great diversity of potential signal molecules, one might expect a given molecule to acquire signal function only occasionally in evolution. However, it is not uncommon to find that members of the same class of molecule or even the same molecular species have signal function in phylogenetically diverse animals. The role of purine nucleotides as chemosensory signals epitomizes this point. Guanosine 5′-monophosphate (GMP) synergizes the perceived intensity of monosodium glutamate in human taste, and methyl xanthenes, compounds that inhibit adenosine receptors, enhance sweet taste (Rifkin, B. and Bartoshuk, L. M., 1980). GMP and other purine nucleotides also increase the binding of glutamate to its receptors isolated from bovine taste papillae by several fold (Torii, K. and Cagan, R. H., 1980). Slime molds use adenosine 5′-monophosphate as an aggregating signal (Mato, J. M. *et al.*, 1978), while adenosine 5′-triphosphate (ATP) in mammalian blood triggers gorging by blood-feeding insects (Friend, W. G. and Smith, J. J. B., 1982). Finally, lobsters recognize food sources in part based on the ratio of ATP to other adenosine nucleotides in their food (Zimmer-Faust, R. K. *et al.*, 1988), and inosine 5′-monophosphate (IMP)

activates gustatory receptors in marine flatfish (Mackie, A. M. and Adron, J. W., 1978). It is not clear whether such diversity of signaling roles for a single class of molecules reflects the early evolution and retention of specific receptor types, or convergent evolution of different receptor types to recognize especially biologically relevant ligands. Such questions can now be addressed as more chemoreceptor proteins are cloned and functionally expressed (see Section 4.01.3).

Chemical signals are rarely, if ever, single compounds in real-world situations. Rather, they are complex mixtures of compounds, where related signals can contain many of the same components in different ratios (Figure 1). Single chemical compounds can elicit physiological and behavioral responses and are used routinely in the laboratory to experimentally dissect chemosensory function. However, complete biological activity inevitably requires stimulation with complex, multicomponent

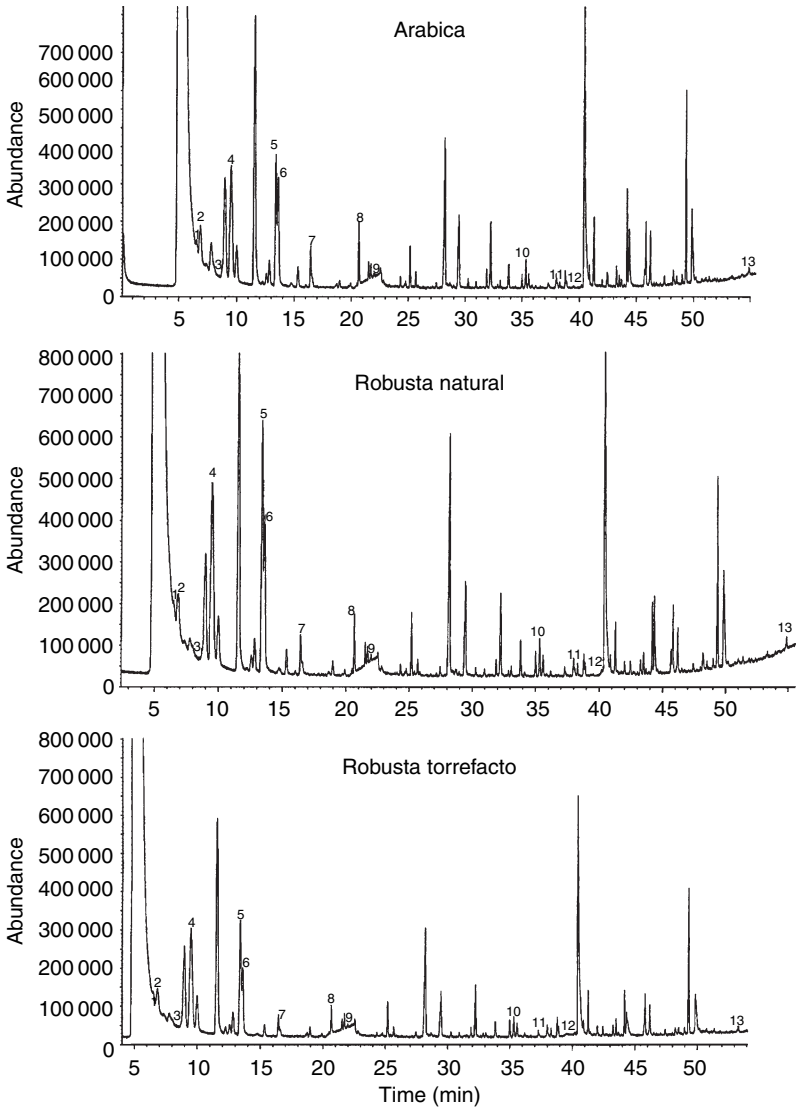

Figure 1 Natural odorants are complex, often highly redundant mixtures. Plots show GC–MS chromatograms of the aroma volatiles of three varieties of espresso coffee: Arabica, Robusta natural, and Robusta torrefacto. Ordinate, absorbance, measuring relative abundance. Abscissa, time in minutes. Similarly numbered peaks in each chromatogram reflect the same compound. Characterization of espresso coffee aroma by static headspace GC-MS and sensory flavor profile. J. Agric. Food. Chem. 49, 5437–5444. Copyright 2001 American Chemical Society.

mixtures of chemical compounds. This generalization holds across phylogenetically diverse species. Relatively simple animals such as cnidarians, jellyfish and sea anemones, can capture and ingest their prey in response to single chemical compounds: glutathione elicits feeding in *Hydra* (Lenhoff, H. M. and Lindstedt, K. J., 1974). But even for these relatively simple animals, discharge of the prey-capturing organs, the cnidia, is regulated by at least two classes of receptors, one for amino and imino acids and another for N-acetylated sugars (Thorington, G. U. and Hessinger, D. A., 1988). Although insect pheromones were originally thought to be silver bullet odorants, as single chemical compounds can attract male to female moths in the field, natural insect pheromones also turn out to be mixtures. For example, the cabbage looper flies upwind in response to major components of the natural pheromone blend, but at least six other components of the female's pheromone gland are required to evoke the full behavioral response of male moths to virgin females (Bjostad, L. B. *et al.*, 1984). Indeed, it is often only subtle differences in the blend ratios of insect pheromones that keep sympatric insect species isolated. Mammals also use complex blends of compounds in pheromone secretions. Here, too, while single putative pheromone components can activate rodent vomeronasal (pheromone) chemoreceptor cells (Leinders-Zufall, T. *et al.*, 2000), it can be difficult to assign behavioral function to individual compounds due to the complexity of mammalian pheromonal secretions and the relatively small contribution of any one component. The scent secretions of tamarins, for example, lack marked differences in the qualitative composition of the marks of individuals of different gender or subspecies, suggesting that this level of behavioral discrimination must be encoded by subtle quantitative differences in the composition of scent mixtures (Belcher, A. M. *et al.*, 1988). Dissecting multicomponent stimulus blends can be daunting due to possible interactions among co-activated elements in the chemosensory pathway. When these interactions are inhibitory, for instance, removal of any one component from a mixture can result in expansion of the relative stimulus strength of the remaining components, masking the ability to detect the component's contribution to the stimulus capacity of the mixture.

4.01.2.2 Dynamics of Chemical Signals

Another hallmark of chemosensory signaling is that the signal is usually intermittent. Indeed, intermittency is fundamental to chemosensation, if not to sensory perception in general, by serving to offset adaptation and sharpen the onset of the signal (Dethier, V. G., 1987). Intermittency is an inherent property of the stimulus field or plume for many animals. Microbes and the smallest of eukaryotes that live within the viscous sublayer of the boundary zone of surfaces, and even those microorganisms that live suspended in the water column, experience stimulus spread that is dominated by diffusion and therefore concentration increases or decreases continuously. All larger animals, however, experience turbulent air or water flow; hence local currents and eddies dominate and perturb stimulus clouds emanating from point sources. Earlier models of odor plumes described the turbulent mixing of the chemical signal into the surrounding water or air as a diffusion process, producing homogeneous clouds with concentration that decreases with distance from the source. However, measurement of stimulus plumes on the scale at which they are encountered by most macroscopic animals in both water and air shows the plumes to be highly discontinuous (Koehl, M. A. R. *et al.*, 2001). As a result, chemoreceptors are only intermittently exposed to the stimulus as the animal moves through the medium or the medium moves over the animal (Figure 2). The specific parameters of the plume structure are medium-dependent and presumably contribute to shaping the dynamic aspects of chemical sensitivity

Figure 2 Odor plumes are highly discontinuous in space and time. Photograph of an odor field in a flume flowing from right to left past the antennule of a lobster. The odorant is a fluorescent dye illuminated by a laser sheet that penetrates the water mass in the plane of the organ. Note the scale of the discontinuities relative to the size of the olfactory organ, the tuft of sensilla on the distal end of the antennule (arrow). Unpublished photograph courtesy of M. Koehl.

in different animals. In addition to intermittency inherent in the stimulus field, animals often actively control the release of chemical signals in a pulsatile manner so as to enhance the intermittency of the stimulus field, further underscoring the fundamental importance of intermittency to chemical sensitivity. This phenomenon typically occurs in association with the release of pheromones, intraspecific chemical signals in which the sender and the receiver of the signal are coevolving. Intermittent release occurs in animals as phylogenetically diverse as slime molds (Mato, J. M. *et al.*, 1978) and insects (Christensen, T. A. *et al.*, 1994). In addition to intermittency inherent in the signal itself, active processes often intermittently gate access of the stimulus to the receptor organ, as considered in Section 4.01.5.2.

4.01.3 Chemoreceptor Proteins

Recognition of this diverse assortment of chemical signals is achieved largely using G-protein-coupled receptors (GPCRs), seven-transmembrane domain proteins that activate G-protein-based signaling cascades when activated by their ligands. Members of the GPCR superfamily recognize a wide range of both external and endogenous chemical signals including general odorants, pheromones, and tastants, as well as endogenous peptide, lipid, neurotransmitter, and nucleotide signals (Vassilatis, D. K. *et al.*, 2003). Several independent expansions of ancestral GPCRs have resulted in a number of sizeable, distantly related chemosensory gene families.

In 1991, Linda Buck and Richard Axel identified a large, diverse family of GPCRs expressed in the rat olfactory epithelium (Buck, L. and Axel, R., 1991) and proposed that they function as odorant receptors (commonly referred to as olfactory receptors, as distinct from a subsequently identified family proposed to be receptors for pheromonal odorants – but see below). This landmark discovery opened the door to the subsequent identification of a number of other chemosensory GPCR families, including insect olfactory and gustatory receptors (Clyne, P. J. *et al.*, 1999; Scott, K. *et al.*, 2001), nematode chemoreceptors (Troemel, E. R. *et al.*, 1995), the V1R and V2R families of mammalian pheromone receptors (Dulac, C. and Axel, R., 1995; Matsunami, H. and Buck, L. B, 1997), and the T1R and T2R families of mammalian taste receptors (Hoon, M. A. *et al.*, 1999; Chandrashekar, J. *et al.*, 2000). With the recent availability of almost complete genome sequences for a variety of species, there has been an explosion in papers describing entire families of chemosensory GPCRs (Table 1). These vast quantities of sequence data allow systematic, in-depth studies of many aspects of chemosensory coding: evolution, receptor–ligand interactions, expression patterns, etc. The size of these chemosensory families varies greatly, from only three GPCRs in the entire yeast proteome (GPR1, a nutritional sensor, and the STE2 and STE3 pheromone receptors) and three receptors in the mammalian T1R family (Liao, J. and Schultz, P. G., 2003) to over 1000 functional members in the rodent olfactory receptor repertoires, comprising up to ~6% of all genes in the genome (Young, J. M. *et al.*, 2003; Rat Genome Sequencing Project Consortium, 2004).

4.01.3.1 Receptor Expression Patterns

In many cases, the function of these gene families was initially postulated based only on expression in the appropriate chemosensory organ. A common assumption has been that the olfactory epithelium and the odorant receptor family expressed therein recognize general (nonpheromonal) odorants and that the vomeronasal organ and its receptor families recognize pheromones. Recent data show that this may be an oversimplification: the vomeronasal organ appears to recognize some compounds which have no known pheromonal activity (Sam, M. *et al.*, 2001) and some pheromones can be recognized after ablation of the vomeronasal organ, perhaps by the nose (Brennan, P. A. and Keverne, E. B., 2004). Additional proof of chemosensory receptor function has been provided for some members of these gene families, for example, by demonstrating functional expression in heterologous cell lines (e.g., Krautwurst, D. *et al.*, 1998), knockout and transgenic rescue experiments (e.g., Mueller, K. L. *et al.*, 2005), or by correlating natural sequence variation with phenotypic variation in chemosensory abilities (e.g., Chandrashekar, J. *et al.*, 2000).

However, the expression pattern of many other genes in these families remains untested, and their functional assignment should be considered tentative as it is based only on sequence similarity. Some systematic studies have been performed to confirm chemosensory expression of subsets of these genes (e.g., Scott, K. *et al.*, 2001) but are not comprehensive. Indeed, expression of some chemosensory receptors has been demonstrated outside the tissue that would

Table 1 Size of selected chemosensory receptor gene families

	No.of genes[a]	*No. of pseudogenes*[a]	*Reference*
Olfactory receptors

be expected based on their family membership. For example, one human pheromone receptor gene appears to be expressed in the olfactory epithelium rather than the vomeronasal organ (Rodriguez, I. *et al.*, 2000), some mammalian olfactory receptors are expressed in nonolfactory tissues, principally the testis (Parmentier, M. *et al.*, 1992), and some bitter taste receptors are expressed in the nose (Finger, T. E. *et al.*, 2003) and gastrointestinal tract (Wu, S. V. *et al.*, 2002). It is possible that some of these reports may reflect promiscuous, irrelevant transcriptional activity, but a recent study provides convincing evidence that the human olfactory receptor hOR17-4 is expressed in testis as well as the nose, responds to the chemical bourgeonal, and allows sperm to undergo chemotaxis toward bourgeonal sources (Spehr, M. *et al.*, 2003). Given their ability to detect a diverse range of ligands, it is perhaps unsurprising that chemosensory receptors have been co-opted to perform other functions.

Within a chemosensory organ, members of some chemosensory gene families exhibit a remarkable and mysterious expression pattern. For example, each neuron in the mammalian olfactory epithelium

probably expresses only one allele of one of the thousand or more genes in the family (Chess, A. *et al.*, 1994; Malnic, B. *et al.*, 1999; Serizawa, S. *et al.*, 2000), although it is still possible that this model is only partially correct (Mombaerts, P., 2004b). This one-neuron, one-gene expression regime ensures that responses to different ligands are segregated into different neurons, allowing fine discrimination between molecules. Axons of neurons expressing the same olfactory receptor converge at a limited number of locations in the olfactory bulb in the brain, thus integrating signals from functionally identical neurons (Mombaerts, P. *et al.*, 1996). Vomeronasal neurons probably follow a similar expression regime (Rodriguez, I. *et al.*, 1999), as do fruitfly olfactory neurons. Most fruitfly neurons each express two receptors: one, Or83b, that is broadly expressed in many olfactory neurons and a second receptor (or occasionally a pair of receptors) selected from among the rest of the gene family (Larsson, M. C. *et al.*, 2004; Goldman, A. L. *et al.*, 2005). The mechanism ensuring singular expression of olfactory receptors is still unclear, although negative feedback may be operating to ensure that once one receptor gene is chosen for expression, no other genes of the family are expressed (Serizawa, S. *et al.*, 2003).

Other families of chemosensory GPCRs, however, are expressed under a less strictly controlled regime. Each mammalian bitter taste receptor cell expresses many or all of the ~30 members of the T2R bitter taste receptor family and is thus broadly tuned to detect a wide range of bitter tastants (Mueller, K. L. *et al.*, 2005). Likewise, each of the nematode worm's 32 chemosensory neurons expresses multiple receptors (Troemel, E. R. *et al.*, 1995). Very few cell types are therefore needed to detect a broad range of chemicals, with the corresponding disadvantage that discrimination between different ligands may be impossible without additional input from other chemosensory modalities. The specificity of neuronal tuning and wiring is discussed further in Section 4.01.6.2.

4.01.3.2 Receptor Structure

It is assumed that regions of the chemoreceptor proteins that vary between members of a family are involved in ligand specification and that regions that are conserved between family members are important for functions common to all members, such as signaling through the G protein (Buck, L. and Axel, R., 1991). Elucidating the three-dimensional structure of many of these GPCRs has proved difficult, as they are transmembrane proteins and in some cases difficult to express in heterologous cell lines. However, distant similarity to rhodopsin, whose crystal structure is known, has allowed some groups to model the structure of a few olfactory receptors (e.g., Floriano, W. B. *et al.*, 2000). Functional studies utilizing these models have been slow to appear, but one study shows that structural considerations can successfully predict which residues are important in determining ligand specificity (Katada, S. *et al.*, 2005).

It has recently become clear that dimerization (both heterodimerization and homodimerization) is important for many GPCRs to function correctly. Dimerization can help achieve proper cell-surface expression, as well as being involved in signal transduction and in determining ligand specificity (Bouvier, M., 2001). The role of dimerization is still largely unknown for the chemosensory receptors, except for the mammalian T1R taste receptor family. This family has three members, T1R1, T1R2, and T1R3; cells expressing T1R1 and T1R3 (presumably functioning as a heterodimer) recognize L-amino acids (Nelson, G. *et al.*, 2002), whereas cells expressing T1R2 and T1R3 recognize sweet tastes (Nelson, G. *et al.*, 2001). The coexpression of olfactory receptor OR83b with other receptors in fruitflies (Larsson, M. C. *et al.*, 2004) and of its ortholog in silk moths (Nakagawa, T. *et al.*, 2005) suggests that these receptors may also function as heterodimers. Heterodimerization among members of the mammalian olfactory and pheromone receptor families is unlikely, as each neuron appears to express only a single gene of the family. There is, however, some evidence to suggest that these receptors dimerize with other GPCR or non-GPCR molecules (Loconto, J *et al.*, 2003; Hague, C. *et al.*, 2004; Saito, H. *et al.*, 2004).

4.01.3.3 Receptor–Ligand Pairings

With the availability of vast numbers of chemosensory receptor sequences, it would be very useful to know which chemical ligand or ligands each receptor responds to. A few general principles emerge from what we know so far about receptor–ligand pairing: receptors may be broadly tuned (each olfactory receptor recognizes multiple odorants) or finely tuned to recognize a single ligand, like the pheromone receptors (Malnic, B. *et al.*, 1999; Leinders-Zufall, T. *et al.*, 2000). In addition, each ligand may activate multiple receptors, each to a different extent. Section 4.01.6.2 discusses these issues in more detail. Several different approaches have been taken to

deciphering receptor–ligand pairings, including coupling expression in heterologous cell lines with functional assays (e.g., Krautwurst, D. *et al.*, 1998), correlating natural or engineered genetic variation in chemosensory receptors with phenotypic variation in chemosensory abilities (Montmayeur, J. P. *et al.*, 2001) and measuring ligand responsiveness of chemosensory neurons expressing particular receptors (Malnic, B. *et al.*, 1999; Bozza, T. *et al.*, 2002; Hallem, E. A. *et al.*, 2004). The success of these approaches has varied between the chemosensory receptor families (Mombaerts, P., 2004a). Many ligands have been identified for mammalian taste receptors and insect olfactory receptors. Unfortunately, heterologous expression (the approach which seems most promising for large-scale identification of receptor–ligand relationships) of many olfactory receptors has proved remarkably difficult. Three recent studies have identified proteins that interact with olfactory or pheromone receptors to facilitate cell-surface expression (Loconto, J. *et al.*, 2003; Hague, C. *et al.*, 2004; Saito, H. *et al.*, 2004). Use of these proteins may allow a much larger number of receptor–ligand pairs to be identified in the near future, findings that are likely to be of great interest and commercial value (Gilbert, A. N. and Firestein, S., 2002).

4.01.3.4 Receptor Gene Family Evolution

As well as greatly informing our knowledge of how chemicals are sensed, the chemosensory families provide fascinating case studies of gene family evolution. Although some chemosensory gene families have remained static over time (e.g., the mammalian T1R family has three members in both human and mouse, and each mouse gene clearly corresponds to a single human gene: Liao, J. and Schultz, P. G., 2003), others have changed greatly even between closely related species. A number of processes have shaped and continue to change these gene families: gene duplication increases the number of family members; accumulation of sequence changes in new gene duplicates creates novel ligand-binding capabilities; deletions and inactivating mutations cause gene loss; and gene conversion erases sequence divergence and/or creates new combinations of sequence variants (Sharon, D. *et al.*, 1999; Young, J. M. *et al.*, 2002). The net result of these ongoing processes is that different species can have very different functional receptor repertoires (Table 1). Figure 3 illustrates how some of these processes have shaped the modestly sized human and mouse T2R bitter taste receptor families.

Differences between species in chemosensory receptor families may be driven by differences in the biological needs of the species – for example, some authors suggest that the loss of functional genes and accumulation of pseudogenes in the primate olfactory and perhaps pheromone receptor families were coincident with the acquisition of trichromatic vision (Zhang, J. and Webb, D. M., 2003; Gilad, Y. *et al.*, 2004), implying that our increased reliance on visual cues made chemosensation at least partially obsolete. For most single-copy genes in a genome, it is possible to identify a unique equivalent in other organisms, a fact that motivates the use of animal models to learn about human biology. The dramatic evolutionary change seen in some of these chemosensory families, together with the fact that even very minor changes in amino acid sequence can alter ligand-binding specificities (Katada, S. *et al.*, 2005), means that studies on individual chemoreceptors may not be particularly applicable across species.

The V1R pheromone receptor family provides perhaps the most striking example of evolutionary change in the chemosensory gene families. Recent studies (Grus, W. E. *et al.*, 2005; Young, J. M. *et al.*, 2005) have shown that rodents have over a hundred functional V1R genes, cows have 30 or more, and opossum at least 49, while dogs have only 8, and humans and chimps close to none. The lack of functional V1Rs in humans and chimps is in keeping with the finding that one of the downstream signaling components, Trp2β, is a pseudogene (Liman, E. R. *et al.*, 1999) and that the vomeronasal organ is absent or vestigial in these species (Trotier, D. *et al.*, 2000). Even between two closely related species, rat and mouse, V1R repertoires reveal dramatic species-specific expansions in some subfamilies, with as many as 23 mouse genes in a V1R subfamily that contains only one rat pseudogene (Grus, W. E. and Zhang, J., 2004; Young, J. M. *et al.*, 2005). It is possible that as two lineages separate during evolution, changes in pheromone receptor gene families establish or reinforce speciation barriers through their role in determining mating behaviors.

These genome-altering processes are ongoing, resulting in polymorphism between different individuals both in receptor sequences and in gene copy number. There are at least 26 human sequence polymorphisms where one variant encodes an apparently functional olfactory receptor and the other variant encodes a pseudogene (Menashe, I. *et al.*, 2003). The

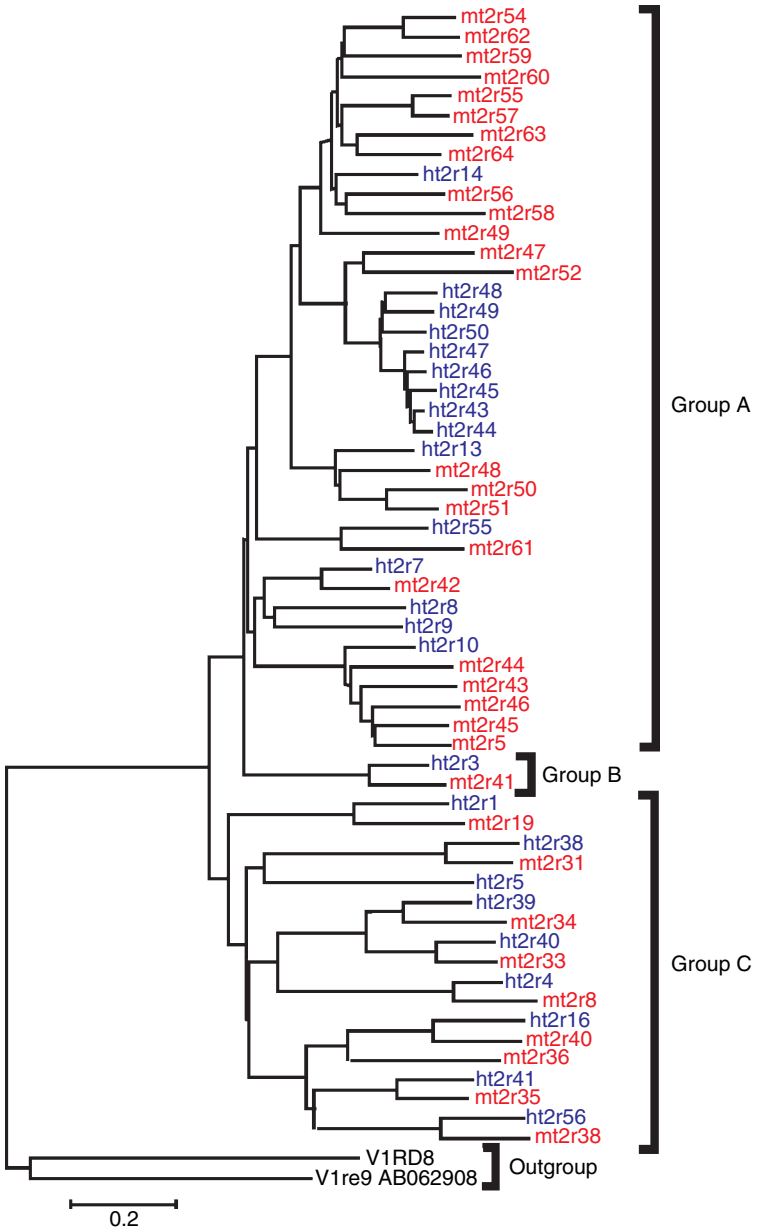

Figure 3 Chemosensory receptor gene families are evolving dynamically. Phylogenetic tree comparing 58 putatively functional human (blue) and mouse (red) bitter taste receptor genes showing that in some branches of the tree (groups B and C) many pairs of one-to-one human–mouse equivalents can be identified, suggesting that these genes have remained stable since the human and rodent lineages diverged. In other branches of the tree (group A), some genes have duplicated several times since the lineages diverged, resulting in clusters of very similar genes and loss of simple, one-to-one equivalence relationships. Stable genes may recognize tastants important to both species, whereas recently duplicated genes might be responsible for the differences between humans and rodents in their gustatory abilities. Adapted from Shi, P., Zhang, J., Yang, H., and Zhang, Y.-P. 2003. Adaptive diversification of bitter taste receptor genes in mammalian evolution. Mol. Biol. Evol. 205, 805–814, with permission from Oxford University Press.

functional implications of some individuals having many more functional olfactory receptors than others are not known, but could be significant. Many other sequence polymorphisms cause a single amino acid change whose functional consequences are currently unknown (e.g., Zhang, X. *et al.*, 2004). Copy number polymorphism of a group of human olfactory receptors has also been described. A recent duplication of a

sequence block found near the ends of several human chromosomes results in different individuals having between 7 and 11 copies of one functional receptor and two pseudogenes, with many copies showing subtle differences in amino acid sequence (Trask, B. J. *et al.*, 1998). Such variation can be difficult to detect; future studies will undoubtedly uncover additional examples of chemosensory receptor gene copy number polymorphism.

One can imagine two possible selective advantages to retaining duplicates of chemosensory receptors. Sequence changes accumulating in a new gene copy might result in novel ligand-binding specificities, providing a selective advantage to an individual who can now detect additional chemical signals. Alternatively, an increase in gene copy number of a given chemosensory receptor might increase the relative number of sensory cells choosing to express that receptor, resulting in increased sensitivity to the corresponding ligand. Evolutionary selective pressures favoring novel amino acid sequence variants are often described as positive selection: when sequence changes are not tolerated, selection is said to be purifying. Initial studies looking at orthologous receptor genes in different species, at paralogous genes within a species, and at polymorphisms between members of the same species are suggestive of positive selection acting on a subset of olfactory receptors (e.g., Hughes, A. L. and Hughes, M. K., 1993; Gilad, Y. *et al.*, 2000), pheromone receptors (Emes, R. D. *et al.*, 2004; Lane, R. P. *et al.*, 2004), nematode chemosensory receptors (Thomas, J. H. *et al.*, 2005), and mammalian bitter taste receptors (Shi, P. *et al.*, 2003). It will be fascinating to learn whether the signs of positive selection observed in these genes correlate with the emergence of novel ligand-binding capabilities.

The functional consequences of changes in the chemosensory receptor families (both in copy number and in amino acid sequence) are mostly unclear at the moment, although some progress is being made in correlating sequence differences and changes in ligand responsiveness. A number of studies describe differential sensitivity to various odorants and tastants, for example, musk, isovaleric acid, and asparagus metabolites (Whissell-Buechy, D. and Amoore, J. E., 1973; Lison, M. *et al.*, 1980; Pourtier, L. and Sicard, G., 1990), but the underlying sequence differences have been identified in only a few cases. Polymorphisms between mouse strains in the gene encoding T1R3 govern their sensitivity to several sweet tastants including saccharin and sucrose (Montmayeur, J. P. *et al.*, 2001). Variation in the mouse mT2R-5 bitter taste receptor affects cycloheximide sensitivity (Chandrashekar, J. *et al.*, 2000), and variation in one of the human T2R genes determines whether the bitter compound phenylthiocarbamide can be tasted (Kim, U. K. *et al.*, 2003).

4.01.4 Peripheral Chemoreceptor Cells

4.01.4.1 Receptor Cell Morphology

The evolution of multicellularity allowed for specialization of cellular function and the appearance of cells dedicated to the detection of chemical cues. Some chemosensory input is mediated by free nerve endings, as in the case of vertebrate trigeminal chemoreceptor neurons, but typically animals have evolved more specialized chemoreceptor cells. Chemoreceptor cells occur both internally, for example, in blood vessels and the gastrointestinal tract, where they monitor the internal milieu, and externally. The general morphology of specialized chemoreceptor cells, whether internal or external, is strikingly similar among species and systems, notwithstanding species-specific differences in their detailed morphology. With one main exception, chemoreceptor cells tend to be primary bipolar neurons in which the dendritic membrane terminates in a filamentous array generally assumed to increase the surface area for stimulus capture, and the axon extends without synapsing to the central nervous system (CNS). Comparing the morphology of olfactory receptor cells in vertebrates and insects and receptor cells in the nematode amphid organ demonstrates this point (Figure 4). Vertebrate taste cells, however, along with their probably evolutionarily related counterparts, solitary chemoreceptor cells (Finger, T. E. *et al.*, 2003), are not bipolar neurons, but secondary-type sensory cells of epithelial origin that make synaptic contact with afferent nerve fibers in the periphery. These cells, too, terminate in filamentous extensions of the plasma membrane. The filamentous extensions of chemoreceptor cells can be either ciliary or microvillar in origin.

4.01.4.2 Receptor Cell Turnover

Chemosensory cells are necessarily exposed to the environment and therefore subject to environmental onslaught. Presumably in response to this stress, they have evolved the ability to turn over and replace

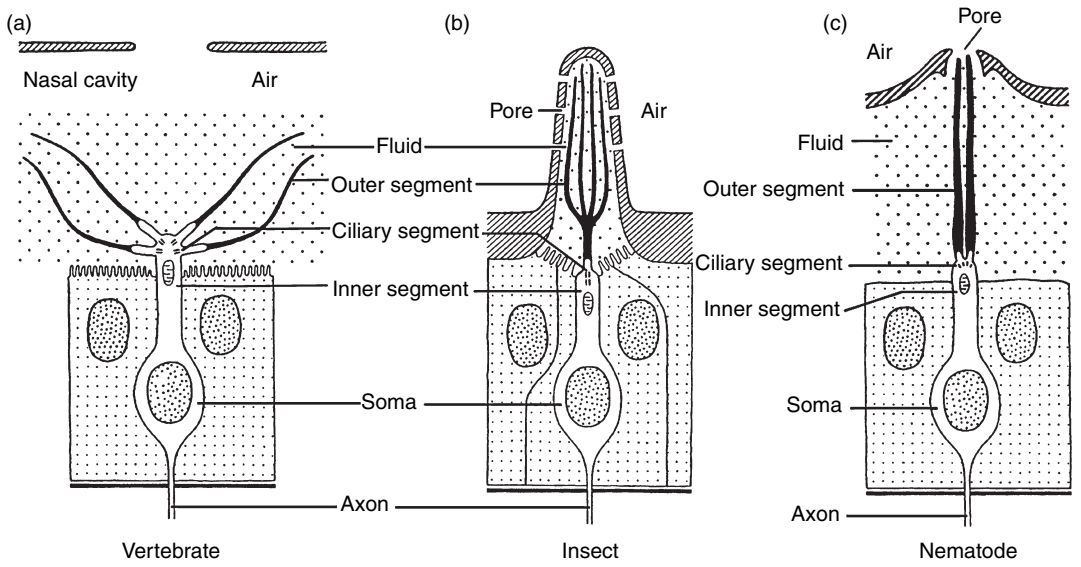

Figure 4 Comparison of primary chemoreceptor neurons in vertebrates, insects, and nematodes. Diagrams compare primary chemoreceptor neurons in the vertebrate olfactory epithelium (a), an insect olfactory sensillum (b), and the nematode amphid organ (c), all drawn to the same size. Note that all are small, bipolar neurons that terminate in a ciliary arbor and send their axon without branching to the CNS. Reproduced from Ache, B. W. 1991. Phylogeny of Smell and Taste. In: Smell and Taste in Health and Disease (*eds.* T. V. Getchell, *et al.*), pp. 3–18. Raven Press. © 1991 Lippincot Williams & Wilkins, with permission.

themselves throughout the life of the animal. Both olfactory and taste receptor cells in all vertebrates are characterized by well-established cycles of birth, maturation, and death (Graziadei, P. P. C. and Monti-Graziadei, G. A., 1978). Given that the olfactory receptor cells are neurons, this feature is remarkable, in that adult neurons generally are not considered to undergo neurogenesis. Receptor cell turnover is not limited to more complex animals, however. The same pulse-labeling technique used to document turnover in vertebrate olfactory receptor neurons shows that chemoreceptor neurons in the anterior tentacles (olfactory organs) of snails also turn over (Chase, R. and Rieling, J., 1986). Lobster olfactory receptor cells (aesthetascs) also turn over, moving from birth, to maturation, to senescence distally along the length of the olfactory organ as the animal grows and adds new segments to the olfactory organ (Steullet, P. *et al.*, 2000). While data are lacking for other species, functional constancy in three such phylogenetically diverse groups of animals argues that turnover is an adaptive property of specialized chemosensory cells that can be expected to occur more generally.

4.01.4.3 Signal Transduction

In addition to detecting the stimulus, chemosensitive cells need to transduce the signal by coupling it to one or more downstream effector molecules. Prokaryotes such as bacteria sense chemical stimuli such as sugars and amino acids differently than most eukaryotes, using transmembrane methyl-accepting chemotaxis proteins (MCPs) linked to a cytoplasmic histidine-aspartate phosphorylating (HAP) system (Wadhams, G. H. and Armitage, J. P., 2004). HAP systems rely on autophosphorylation of a histidine residue and subsequent transfer of a phosphoryl group to an aspartate residue on an associated regulatory protein to generate a response. As detailed in the previous section, eukaryotic chemoreceptor proteins are typically GPCRs that couple to downstream effectors through heteromeric GTP-binding proteins and intracellular second messengers. The second messenger typically targets ion channels that when activated alter the membrane potential of the cell and generate a graded, voltage-dependent response. In multicellular animals with specialized chemoreceptor cells, this leads to the generation of all-or-none electrical signals (action potentials or spikes) that propagate to the CNS with a frequency that is proportional to the magnitude of the graded change in membrane potential. Action potentials are generated within the sensory cell in the case of primary sensory receptor neurons or through synaptic coupling to a neuron in the case of secondary sensory receptor cells.

Two main intracellular signaling pathways are used in eukaryotic cells, utilizing cyclic nucleotides and phosphoinositide-derived signals. Both pathways seem to operate in a diverse range of species, with no clear evolutionary trend in the use of one signaling cascade over the other. Cyclic nucleotide signaling in chemosensory transduction is best understood in vertebrate olfactory receptor neurons (Figure 5(a)). The target of cyclic nucleotide signaling in these cells is the olfactory cyclic nucleotide-gated ion channel

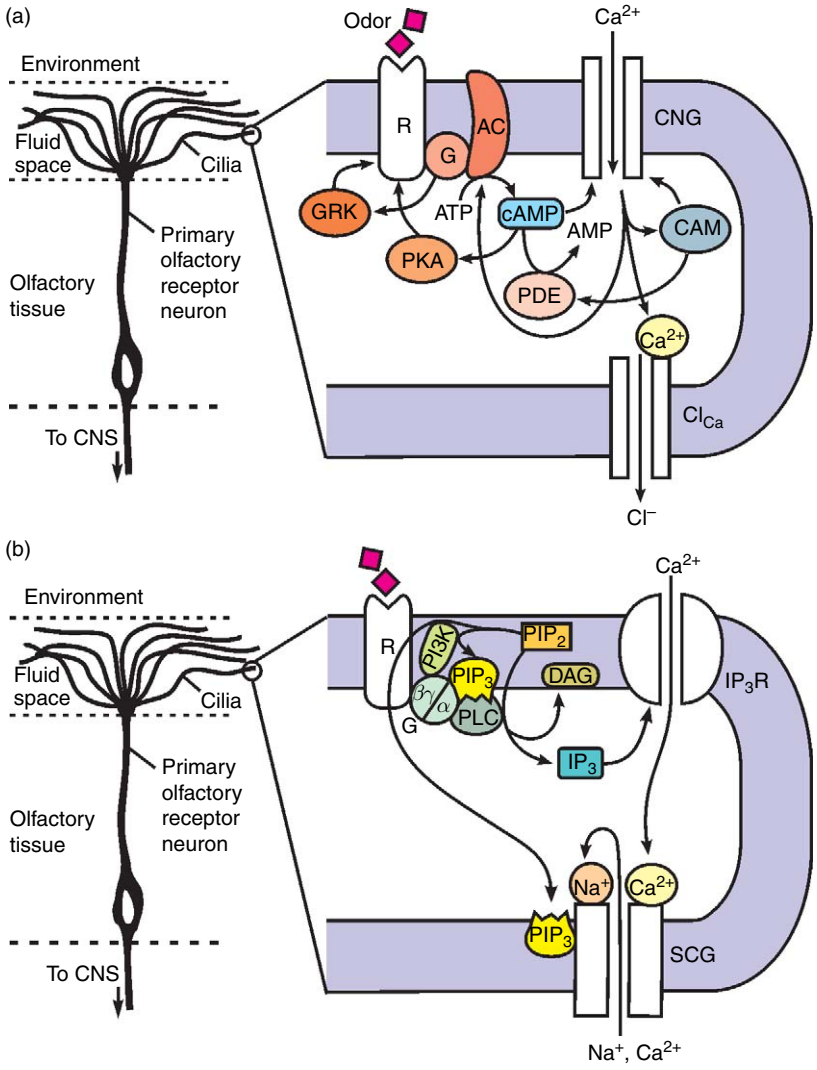

Figure 5 Two intracellular signaling cascades implicated in chemosensory transduction. (a) Diagram of cyclic nucleotide signaling in the transduction compartment (olfactory cilia) of vertebrate olfactory receptor neurons. Odorant molecules bind to a receptor protein (R) coupled to an olfactory specific G_s-protein (G) and activate a type III adenylyl cyclase (AC), increasing intracellular cAMP levels. cAMP targets an olfactory-specific cyclic-nucleotide gated ion channel (CNG), a nonselective cation channel that increases intracellular calcium and secondarily activates a calcium-activated chloride channel thought to carry the majority of the transduction current. Other regulatory pathways are also shown. (b) Diagram of phosphoinositide signaling as currently understood in the transduction compartment (outer dendrite) of lobster olfactory receptor neurons. Odorant molecules bind to a receptor protein (R) coupled to a G_q-protein and activate both phospholipase-C (PLC) and phosphoinositide 3-OH kinase (PI3K) to generate diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3), and phosphatidylinositol 3,4,5-trisphosphate (PIP_3), respectively, from phosphatidylinositol 4,5-bisphosphate (PIP_2). PIP_3 in concert with release of extracellular calcium from a plasma membrane IP_3 receptor (IP_3R) targets a lobster homolog of a transient receptor potential channel, a nonselective cation channel that is modulated by both sodium and calcium (SGC) and is thought to carry the majority of the transduction current. Details of these pathways vary in other receptor cells and other species.

(Zufall, F. *et al.*, 1994), activation of which allows calcium entry into the cell that secondarily activates a calcium-activated chloride current in a two-step activation cascade. The latter current generates much of the excitatory receptor potential (Reisert, J. *et al.*, 2003). Cyclic nucleotide signaling also appears to operate in chemosensory transduction in slime molds (Newell, P. C. *et al.*, 1988), protozoans (*Paramecium*, Yang, W. Q. *et al.*, 1997), nematodes (*C. elegans*, Komatsu, H. *et al.*, 1999), and arthropods (lobster, Boekhoff, I. *et al.*, 1994). The role of phosphoinositide signaling in chemosensory transduction is less well established than that of cyclic nucleotide signaling and is perhaps best understood in mediating excitation of crustacean olfactory receptor cells (Figure 5(b)). There, the target of phosphoinositide signaling is a calcium-sensitive presumptive lobster homolog of the TRP family of ion channels (Bobkov, Y. V. and Ache, B. W., 2005). Odorants activate both the PLC- and the PI3K-mediated arms of this signaling cascade, allowing the channel to be targeted directly by 3-phosphoinositides and/or indirectly via gating of extracellular calcium from an associated plasma membrane $InsP_3$ receptor (Munger, S. *et al.*, 2000). Phosphoinositide signaling has also been implicated at least indirectly in chemosensory transduction in other, phylogenetically diverse species, including slime molds (Newell, P. C. *et al.*, 1988), nematodes (Colbert, H. A. *et al.*, 1997), insects (Boekhoff, I. *et al.*, 1990), fish (Bruch, R. C. and Teeter, J. H., 1989), mammalian vomeronasal receptor cells (Lucas, P. *et al.*, 2003), and receptor cells in the main olfactory epithelium of mammals (Spehr, M. *et al.*, 2002).

A question that has been the subject of some controversy, for example, in taste transduction in mammals (Zhang, Y. *et al.*, 2003), is whether individual receptor cells use both cyclic nucleotide and phosphoinositide signaling cascades for chemosensory transduction. There is no *a priori* need for a receptor cell to utilize multiple signaling cascades to encode the magnitude of receptor binding. However, when coupled to different receptors or to different sites on the same receptor in a ligand-specific manner, multiple signaling cascades can allow receptor cells to integrate responses to multiple chemical stimuli with potentially important consequences for quality coding (see Section 4.01.6.2). Many diverse species appear to utilize both signaling pathways, including slime molds (Newell, P. C. *et al.*, 1988), arthropods (lobster, Boekhoff, I. *et al.*, 1994), and mammalian olfactory (Spehr, M. *et al.*, 2002), and taste (Gilbertson, T. A. *et al.*, 2000) receptor cells, suggesting that having both signaling pathways in the same cell may serve a fundamental role in chemosensory signaling, although one that is still being resolved.

Sensitivity to some chemicals can be mediated through non-GPCR-based pathways. Odor- or taste-gated ion channels have been proposed as a potential mechanism of chemosensory transduction in a small number of cases (e.g., Teeter, J. H. *et al.*, 1990), although ionotropic chemoreceptors do not appear to play a major role in chemosensory transduction. The best understood exceptions to the involvement of GPCRs in chemosensory signaling involve direct action of the stimulus on the cell without the need for cell-surface receptors. Ions such as Na^+ and protons serve as salt and sour stimuli, respectively, in mammalian taste. These ions are thought to permeate through steady-state ion channels and alter the membrane potential directly without the involvement of downstream signaling cascades (Gilbertson, T. A. *et al.*, 2000). While ions might act similarly in other species, this question has not received the same degree of attention as it has in mammalian taste receptor cells. It is known, however, that ammonia can penetrate the cell membrane of protozoans such as the ciliate, *Paramecium*, and alter chemotaxis through alkalization of the cytoplasm (Van Houten, J. L., 1998), suggesting that nonreceptor-mediated chemical sensitivity can work in parallel with receptor-mediated chemosensitivity in diverse species.

4.01.5 Perireceptor Processes

Activation and adaptation of chemoreceptor cells can be influenced by mechanical and biochemical events in the vicinity of the receptor cells. By modulating or filtering the chemical signal that actually reaches the site of transduction, these so-called perireceptor processes are essential components of chemosensory systems (Carr, W. E. *et al.*, 1990a). The importance of perireceptor processes in chemical sensitivity is still being appreciated, but these processes, too, appear to be conserved in diverse species, suggesting that they are fundamentally important in chemical signal detection.

4.01.5.1 Mechanical Processes

As noted earlier, chemoreceptor cells are seldom, if ever, continuously exposed to the stimulus, and the

resulting intermittency of stimulation is fundamental to how they operate. In addition to the signal itself being intermittent, active processes often result in intermittent access of the stimulus to the receptor cells. Receptors within the taste papillae on the surface of the tongue, for example, are only intermittently contacted by the stimulus, the food bolus, when food is actively moved around the oral cavity by tongue movements and mastication. Perhaps the best known example of active intermittent sampling is sniffing in mammalian olfaction, a process that has an integral effect on odor processing in the olfactory bulb and lateral hypothalamus (Macrides, F. and Chorover, S. L., 1972) and that optimizes the perception of odor intensity in humans (Laing, D. G., 1985). A diverse range of active processes in other vertebrate and invertebrate species gate access of stimulus to their respective olfactory organs. Snakes flick their tongue, periodically bringing airborne volatiles to the vomeronasal organ (Kubie, J. and Halpern, M., 1975). Salamanders actively ventilate their olfactory and vomeronasal receptor cavities at 1–2 Hz (Kauer, J. S. and Shepherd, G. M., 1977). Octopus (Chase, R. and Wells, M. J., 1986) and cyclosmate fish like flounders (Doving, K. B. and Thommesen, G., 1977) actively pump water through their siphons or nasal chamber, respectively. Moths fan their wings to enhance air penetration through their olfactory sensillae (Loudon, C. and Koehl, M. A. R., 2000) and decapod crustaceans flick their olfactory organ (Schmitt, B. C. and Ache, B. W., 1979). The ubiquity of active gating suggests that time-locked intermittency is somehow fundamental to the recognition and discrimination of chemosensory signals. Indeed, the dynamic properties of downstream elements in the transduction cascade as well as the kinetics of synaptic interactions in the CNS may be tuned to such intermittency.

4.01.5.2 Biochemical Processes

The apical ends of chemoreceptor cells typically do not project into the environment directly, but instead into a fluid-filled compartment that in turn contacts the environment. This holds even for aquatic animals where desiccation and/or osmotic challenge would not necessarily be a problem. The composition of the fluid bathing the receptor cells is actively regulated by the organism and can contain enzymes, buffers, and other molecules capable of interacting with and potentially modifying the chemical signal (Pelosi, P., 1996). Best known of these are the so-called odorant-binding proteins (OBPs), small soluble dimeric proteins that bind hydrophilic odorants. OBPs have been characterized in human olfactory mucus (Briand, L. *et al.*, 2002), as well as in most terrestrial animals, including sheep, pigs, cows, rats, frogs, insects, snails (Pelosi, P. and Maida, R., 1990), and elephants (Lazar, J. *et al.*, 2002). The common molecular properties and the occurrence of OBPs in such a phylogenetically diverse range of terrestrial animals suggest they played an important role in the terrestrialization of olfaction. OBPs in moth and rat are not homologous, suggesting the common molecular properties of at least these OBPs evolved convergently (Pevsner, J. *et al.*, 1988). Given the homology of mammalian OBPs to the lipocalin superfamily of proteins (Tegoni, M. *et al.*, 2000), it has often been assumed that OBPs serve to bind and transport hydrophobic ligands through the aqueous perireceptor environment. However, OBPs have also been proposed to serve other functions, including serving as molecular filters to specify and perhaps facilitate stimulus access to receptors (Vogt, R. G. *et al.*, 1990). Another family of proteins, pheromone-binding proteins (PBPs), helps deliver volatile pheromone compounds. Some OBPs and PBPs are similar in sequence, suggesting that members of the OBP family may serve as molecular filters for pheromones rather than for general odors (Pelosi, P., 2001). However, the function of OBPs remains unclear for any type of odorant.

The perireceptor fluid also contains degradative enzymes that could deactivate the stimulus (Carr, W. E. S. *et al.*, 1990b). These, too, occur in phylogenetically diverse species. Slime molds, for example, aggregate in response to the pulsatile release of cAMP from calling amoeboid cells. Both membrane-associated and soluble phosphodiesterases rapidly inactivate cAMP in the vicinity of the source, thereby sharpening the chemotaxic gradient (Janssens, P. M. W. and Van Haastert, P. J. M., 1987). An esterase (Vogt, R. G. *et al.*, 1985) and an aldehyde oxidase (Rybczynski, R. *et al.*, 1989) that rapidly degrade pheromones have been identified in the perireceptor fluid or lymph of insect olfactory receptor cells. Ectonucleotidases in the lobster olfactory organ progressively dephosphorylate adenosine nucleotides (feeding cues) into nonstimulatory adenosine (Trapido-Rosenthal, H. G. *et al.*, 1987). Finally, the mammalian olfactory epithelium contains many catabolic enzymes that could potentially degrade various classes of odorants, including an olfactory-specific homolog of uridine

diphosphate-glucuronosyl transferase (Dahl, A., 1988) and several isoforms of cytochrome P450 enzymes. Lower levels of cytochrome P450 are also found in the mammalian vomeronasal organ (Gu, J. *et al.*, 1999). It remains to be determined whether such degradative enzymes act on the signal *per se*, that is, whether they rapidly terminate the signal and therefore alter its dynamic properties or whether they serve to maintain the perireceptor space over longer intervals of time by minimizing the background levels of stimuli and/or removing potentially toxic environmental compounds.

4.01.6 Processing of Chemosensory Information

4.01.6.1 Central Neural Organization

Chemosensory organs are sometimes associated with a peripheral nerve net or plexus, as occurs, for example, in mollusks, resulting in an afferent signal that already reflects some degree of integration. Such peripheral chemosensory integration is best characterized in the vertebrate taste system, where groups of taste receptor cells, supporting cells, and their associated neural elements form a distinct end organ, the taste bud, with synaptic and ephaptic connections suggestive of interactions among the cells reminiscent of those in the vertebrate retina (Huang, Y. J. *et al.*, 2005). Accordingly, afferent taste nerves transmit an integrated signal to the CNS. The more common organizational plan of chemosensory pathways, however, is for the primary chemosensory afferents to project without synapsing to the CNS, shifting the majority of signal processing to the brain. We are only just beginning to understand how the brain processes chemosensory information, but new molecular and imaging approaches to studying the CNS are poised to rapidly increase our level of understanding of the central neural substrates for molecular recognition (e.g., Zou, Z. *et al.*, 2001).

One system that has been particularly well studied in several, phylogenetically diverse animals is the first olfactory relay – the vertebrate olfactory bulb and its functional equivalent in arthropods, the insect antennal lobe, and the crustacean olfactory lobe. The rather striking analogy of the vertebrate olfactory bulb and the insect antennal lobe was noted by neuroanatomists as early as 1883 (Belloncei, G., 1883), even though some differences are apparent. The mammalian olfactory bulb is laminarly organized with neurons integral to the neuropil, the synaptic-containing region of the bulb (Figure 6(a)), while the

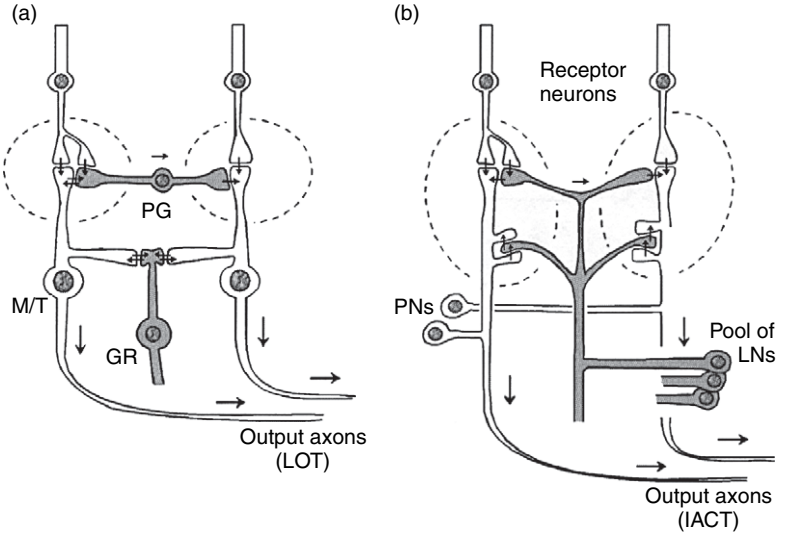

Figure 6 Comparison of the first olfactory relay in insects and mammals. (a) Diagram of the mammalian olfactory bulb showing receptor cells contacting mitral/tufted (M/T) and periglomerular (PG) cells in glomerularly organized neuropil (dashed circles), creating parallel output pathways in the lateral olfactory tract (LOT), transected by two levels of lateral inhibitory connections, one formed by the PG cells and the other by granular (GR) cells. (b) Diagram of the insect antennal lobe drawn in the same format as (a) showing essentially the same overall organization of the projection neurons (PNs) and various types of local interneurons (LNs). From Christensen, T. A. and White, J. 2000. Representation of Olfactory Information in the Brain. In: The Neurobiology of Taste and Smell, 2nd edn. (*eds.* T. E. Finger, W. L. Silver, and D. Restrepo), pp. 201–232. Wiley-Liss, Inc. Copyright 2000 John Wiley, Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

insect antennal lobe lacks laminar organization, and its neurons are peripheral to the neuropil, with the synapses confined to the glomeruli (Figure 6(b)). To see the organizational similarity emerge, one has to look through these characteristic differences in the organization of vertebrate and invertebrate neuropil (Christensen, T. A. and White, J., 2000). Doing so shows that in both the olfactory bulb and the antennal lobe, the primary olfactory afferents strongly converge into glomerularly organized neuropil where they branch profusely and terminate on both projection neurons and local interneurons. As mentioned above, glomeruli are formed by the convergence of olfactory neurons that have chosen to express the same receptor and thus integrate signals from functionally identical neurons. Glomeruli in both structures contain the same complex, serial reciprocal synapses (Pinching, A. J. and Powell, T. P. S., 1971; Tolbert, L. P. and Hildebrand, J. G., 1981). The projection neurons take the output of one or a few (depending on the species) glomeruli directly to the next synaptic level, the olfactory cortex in mammals and the corpora pedunculata in arthropods. Local interneurons inherent to the neuropil create two levels of lateral connectivity across the afferent fiber-projection neuron throughput pathway. Interestingly, while most of the olfactory glomeruli tend to be morphologically uniform, one glomerulus in each structure, the modified glomerular complex in mammals (Teicher, M. H. *et al.*, 1980) and the macroglomerular complex in some insects (Matsumoto, S. G. and Hildebrand, J. G., 1981), is greatly enlarged and processes input from pheromone receptors. Many of these organizational features also occur in the first olfactory relay in terrestrial snails, the protocerebral lobe (Chase, R. and Tolloczko, B., 1986), further underscoring the potential utility of this organizational plan to olfactory signal detection.

The apparent conservation between species in the anatomical organization of the first olfactory relay suggests it has important functions in olfactory signal detection. Clearly, the synaptic connections within and among glomeruli are integral to the way olfactory information is processed at this level of the olfactory pathway, and molecular and imaging approaches are actively being used in both vertebrate and invertebrate models to decipher the role(s) of olfactory glomeruli in odor recognition (e.g., Bozza, T. *et al.*, 2004). While the functional role(s) of the first olfactory relay still remain to be understood, some conserved functional features can be identified. One such conserved feature is presynaptic afferent inhibition (PAI), in which the terminals of the primary afferent fibers are contacted by inhibitory local interneurons. One distinct subpopulation of the local interneurons that laterally connect olfactory glomeruli mediates PAI in animals as diverse as mammals (Hayar, A. *et al.*, 2004) and lobsters (Wachowiak, M. *et al.*, 1997). There is functional evidence for PAI in lobsters, turtles, and rodents, and in both vertebrates and invertebrates, this involves paired neurotransmitters (Wachowiak, M. *et al.*, 2002). As is commonly the case in phylogenetic comparisons, the cellular mechanism differs even though the principal holds. PAI in lobsters reflects ionotropic receptor-mediated changes in membrane potential, while in the turtle, PAI reflects metabotropic receptor-mediated changes in intracellular calcium (Wachowiak, M. and Cohen, L. B., 1999).

4.01.6.2 Quality Coding

The question of how the molecular identity of a chemical stimulus is coded by the nervous system is fundamental to understanding chemical sensitivity. In spite of recent progress, however, the answer remains elusive for both smell and taste. The central argument is whether the identity or quality of the chemical signal is coded by labeled lines, in which the particular cell type that is activated specifies or labels the stimulus, or whether the quality of the stimulus is not inherent in any particular cell type but rather is represented by the pattern of activation across a population of cells with relatively broad overlapping response spectra in a combinatorial manner (Figure 7). Operationally, labeled line or combinatorial coding is often considered in reference to a particular level of a chemosensory pathway, e.g., the tuning or range of ligands that activate individual receptor cells, but the concept ultimately applies more to the overall coding strategy for the sensory modality in question. In that regard, labeled line and combinatorial coding are not mutually exclusive and could be integrated within a given level or across levels of a chemosensory pathway, as seen in the coding of odor mixtures in the lobster olfactory pathway (Derby, C. D., 2000). Both strategies appear to be used in a wide range of species. The choice of coding strategy may be more closely tied to the informational importance of the stimulus than the phylogenetic position of the species. Labeled line coding is expensive as it requires dedicated neural space and therefore may serve to detect stimuli of

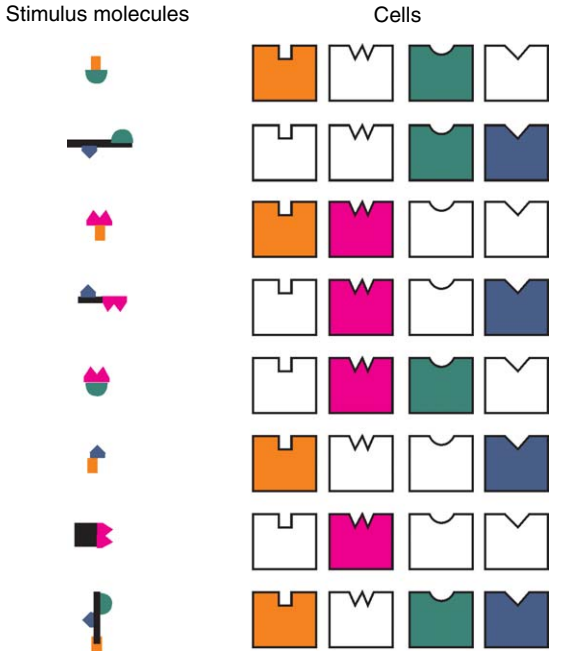

Figure 7 Combinatorial coding. Diagram of hypothetical stimulatory molecules with some shared as well as some different molecular features (left) and the different patterns of neural activity each molecule would elicit across a hypothetical population of four receptor cells each expressing one receptor protein tuned to a particular molecular feature (right). The cells that are activated by each molecule are colored. Note that many molecules activate multiple receptors, and each molecule generates a unique pattern of activity across the population of receptor cells. Reproduced from Malnic, B., Hirono, J., Sato, T., and Buck, L. B. 1999. Combinatorial receptor codes for odors. Cell 96, 713–723, with permission from Elsevier.

especially strong adaptive value, for example, the detection of salt in terrestrial mammals, or of pheromones in short-lived insects that hatch, mate, and die.

It is now generally agreed that odorants are coded in a combinatorial manner. This long-standing idea received strong support from recent evidence that individual mammalian olfactory receptor cells expressing a single, identified receptor protein can be activated by multiple different odorants and that individual odorants activate multiple receptor cells expressing different receptor proteins (Malnic, B. *et al.*, 1999). Similar findings for the olfactory receptors of insects (Hallem, E. A. *et al.*, 2004) and fish (Luu, P. *et al.*, 2004) suggest that combinatorial coding has been conserved in the evolution of olfaction. Combinatorial coding is also used in other chemosensory systems, as demonstrated by the hundreds of receptor proteins expressed in the nematode *C. elegans*, which has only 32 chemoreceptor cells in the entire adult worm (Bargmann, C. I. and Kaplan, J. M., 1998).

Chemosensory receptor cells can have two (bipolar) modes of signaling, excitation and inhibition. Such flexibility adds to the combinatorial possibilities in chemosensory coding and has been observed in a phylogenetically diverse range of species. Odors inhibit as well as excite olfactory receptor cells in mollusks (squid, Lucero, M. T. *et al.*, 1992), arthropods (insects, lobsters, McClintock, T. S. and Ache, B. W., 1989; De Bruyne, M. *et al.*, 2001), fish (Kang, J. and Caprio, J., 1995), amphibians (frogs, Sanhueza, M. *et al.*, 2000), and mammals (rats, Duchamp-Viret, P. *et al.*, 1999). The cellular mechanism(s) that mediate this opponent input are still being explored, but as noted earlier, this phenomenon can be explained in at least some species by ligand-directed activation of opposing intracellular signaling pathways. Different chemical stimuli attract and repel even single-celled organisms such as *Paramecium* by polarizing the cell in opposite directions (Van Houten, J. L., 1998).

How tastants are coded has focused mainly on the mammalian gustatory system, where the ability to distinguish the so-called basic tastes – sweet, sour, bitter, salt, and amino acids – spawned the search for cell types coding for these qualities. Recent evidence suggests that bitter, sweet, and amino acid tastes are coded by labeled lines, at least at the level of the receptor cells (Zhang, Y. *et al.*, 2003; Mueller, K. L. *et al.*, 2005). It is possible, for example, to induce a sweet response, that is, attraction, to bitter stimuli that otherwise evoke aversion by genetically engineering a mouse to drive the expression of a bitter receptor in taste receptor cells that normally express sweet receptors. This finding implies that taste cells that normally express sweet taste receptors are hardwired to elicit attraction independently of what receptors or ligands are present. Consistent with this interpretation, some cells in the taste nerve as well as in the second gustatory relay in rodents, the parabranchial nucleus (PBN), are best for, that is, respond most strongly to, specific taste qualities and could be considered to function as labeled lines for those qualities (Smith, D. V., 1985). However, the labeled line principle may not exclusively hold. Smith and others found that no one cell type in the PBN can distinguish similar-tasting compounds and that other, more broadly tuned cells contribute to a combinatorial code for taste quality. In multivariate analyses, he found, for example, that sweet-best PBN neurons can distinguish sweet tasting compounds in a

panel of tastants, but neither these nor the more broadly tuned cells by themselves were able to differentiate sweet from, say, bitter tasting compounds. Only both types of cells together contained sufficient information to differentiate sweet from bitter. These and other findings argue that, like odorants, tastants are coded in a combinatorial manner. Unfortunately, little additional insight into taste coding is available from other vertebrates or invertebrates, in large part due to the difficulty inherent in defining taste quality in nonmammalian species. In an extensive analysis of phytophagous caterpillar species with differing types of food preference, it was not possible to identify specific taste receptor cell types that could account for food preference, even in strict monophagous species, arguing that food preference was not based on a labeled line code (Dethier, V. G. and Crnjar, R. M., 1982). On the other hand, a distinct set of neurons in the main taste organ of flies, the labellum, exhibit potential hallmarks of a labeled line for sweet taste. These neurons express a receptor for trehalose, project to a distinct brain region, and mediate responsiveness to sweet (as defined by mammalian behavioral responses) compounds, while being unresponsive to bitter compounds (Thorne, N. *et al.*, 2004). Whether tastants are coded using a common strategy or whether coding strategy is context- and/or species-dependent remains an open question.

4.01.7 Chemosensory-Mediated Behavior and Plasticity

As noted earlier, phylogenetically diverse animals use chemical stimuli to communicate in an amazingly diverse array of behavioral contexts. The ability of pheromones to convey remarkably specific information about gender, status, and individuality is just one particularly noteworthy example. Primate secretions are sufficiently complex to allow social information to be communicated by unique blends of the major and minor constituents of these secretions (Epple, G. *et al.*, 1989). Chemosensory-mediated social recognition in mammals is better understood in mice, where genes of the major histocompatibility complex (MHC), the genes controlling immunological identity, have been known for some time to determine pheromone-mediated mating preference (Yamaguchi, M. *et al.*, 1981; Yamazaki, K. *et al.*, 1989). Recently, MHC class I peptides in the urine of mice, the peptides that mediate individual recognition in pregnancy block, were shown to activate a subset of vomeronasal chemoreceptor cells (Leinders-Zufall, T. *et al.*, 2004). Pheromones also mediate individual recognition in cnidarians – the jellyfish, corals, and sea anemones. These animals can reproduce asexually by budding and form large colonies or mats of genetically identical individuals. Clear borders between mats of such sea anemone individuals are actively maintained by intraspecific aggression (Francis, L., 1973). This behavior is triggered when distinct chemoreceptors on the tentacles contact foreign individuals in neighboring mats as the animals wave about (Lubbock, R., 1980), suggesting this is a chemosensory-mediated behavior. Thomas L. (1974) proposed the existence of a fundamental similarity between immunorecognition and chemical sensitivity, suggesting that the histocompatibility genes on which immunorecognition is based evolved to protect the integrity of the individual organism, for example from invasion of potential symbionts, by strategies such as imparting a characteristic odor to each individual. The presence of individual-specific pheromones in animals as phylogenetically diverse as coelenterates and mammals gives credence to his hypothesis.

All animals must adapt to changing environments, so it is not surprising that plasticity is a hallmark of chemosensory-mediated behavior. Behavioral plasticity encompasses a broad range of phenomena that do not necessarily share a common neural substrate. These phenomena range from simple alterations in levels of responsiveness such as sensitization and habituation to imprinting, to more complex forms of associative leaning. One type of plasticity of particular relevance to chemical sensitivity is food aversion learning, the long-term retention of experience gained from a single association between ingestion and subsequent illness that most humans have experienced at one time or another. This phenomenon is also well documented in other mammals, especially in coyotes and rats where it has been studied in the context of bait shyness (Garcia, J. *et al.*, 1974). Food aversion also occurs in blue jays after eating toxic monarch butterflies. They subsequently seize but no longer consume monarchs due to the distinctively bitter taste of the toxic cardiac glycosides the butterflies sequester from the plants on which they feed (Brower, L. P. and Glazier, S. C., 1975). Food aversion even occurs in mollusks, where a single meal of carrot followed by exposure to quinidine sulfate, an irritant, causes the terrestrial slug, *Limax*, to reduce its preference for carrots (Gelperin, A., 1975). Interestingly, food aversion in slugs shows all

the classical characteristics of food aversion in mammals, including rapid onset, the need for only a single pairing of the conditioned (CS) and unconditioned (US) stimulus, a long CS–US interval, persistence without reinforcement, association restricted to a specific CS, and enhancement through co-association with odor cues. Thus, even complex, associative chemosensory-mediated behavior, and possibly its underlying neural circuitry, can transcend broad species differences.

The early stages of olfactory processing are involved in experience-dependent behavioral modification in animals as phylogenetically diverse as mammals and mollusks. Early odor experience in rat pups, for example, dramatically enhances later responses of the animals to the familiar odor, a phenomenon that is accompanied by specific physiological and morphological changes in the circuitry of the olfactory bulb (Coopersmith, R. and Leon, M., 1984). Similarly, the gastropod mollusk, *Limax*, can also be behaviorally conditioned to odors. Indeed, it is possible to condition the brain after it has been isolated from the animal and placed in a recording chamber using the same paradigm used to condition the intact animal (Gelperin, A., 1986), allowing direct access to the altered neural circuitry for biochemical and biophysical analyses. The network of olfactory interneurons in the protocerebral lobe of the slug shows coherent oscillations in local field potentials (LFPs) that can be modified by odor input, not unlike similar coherent LFP oscillations observed in insects and a wide array of vertebrates (Figure 8). The

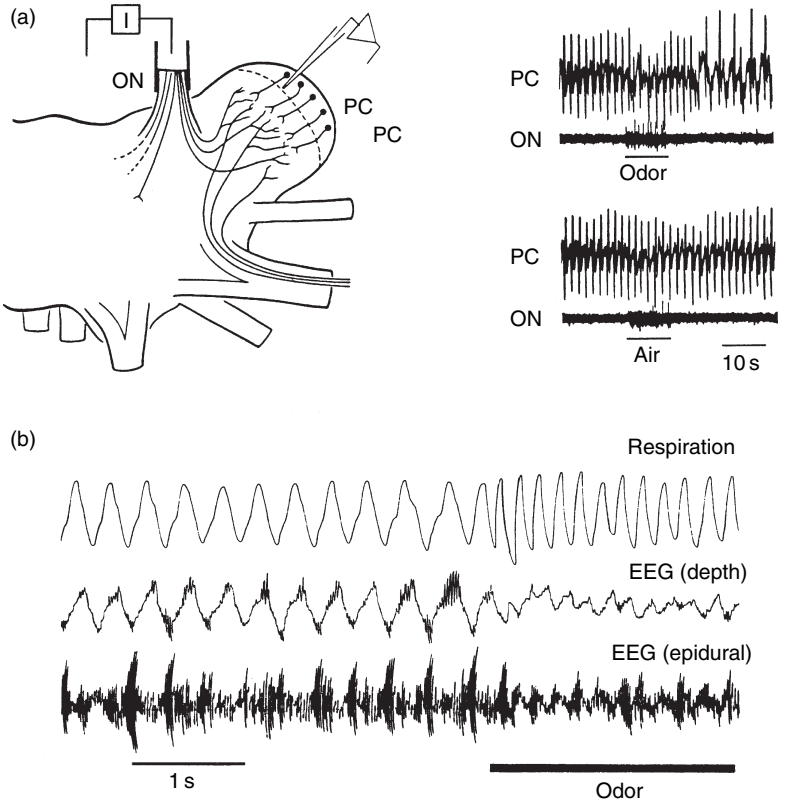

Figure 8 Dynamical structure of neural activity in the first olfactory relay implicated in odor discrimination and memory. (a) Left panel: diagram of the cerebral ganglion of a terrestrial slug showing a recording electrode in the protocerebral lobe (PC) and a stimulating electrode on the olfactory nerve (ON, shown here cut for electrical stimulation but normally intact). Right panel: recordings of neural oscillations from the preparation showing responses to potato odor (upper pair of traces) and clean air (lower pair of traces). Note the odor-induced changes in the waveform and frequency of the PC lobe oscillations. (b) Recordings from the rabbit olfactory bulb showing the 3–7 Hz respiratory rhythm (upper trace) and 40–80 Hz oscillatory EEGs recorded at depth (middle trace) and on the surface (bottom trace) of the bulb. Note the odor-induced changes in the waveform and frequency of the oscillatory field potentials. Reproduced from Ache, B. W. 1991. Phylogeny of Smell and Taste. In: Smell and Taste in Health and Disease (*eds.* T. V. Getchell, *et al.*), pp. 3–18. Raven Press. © 1991 Lippincot Williams & Wilkins, with permission.

presence of neural circuitry at the same synaptic level of the olfactory pathway with similar dynamical structure in animals as phylogenetically diverse as mollusks, insects, and mammals suggests that local circuit oscillations or the coherent neural activity that underlies them play a fundamental role in odor discrimination (Laurent, G., 2002). Odor memory has been shown to be associated with olfactory network dynamics in both insects (locusts, Stopfer, M. and Laurent, G., 1999) and mollusks (slugs, Gelperin, A., 1999). This research is leading to testable predictions as to how oscillatory dynamics may influence the acquisition and storage of odor memory.

4.01.8 Overview

In this chapter, we focus on features shared by different chemosensory systems and different species to reveal the guiding principles of chemical detection. Evolutionary conservation of these shared features presumably reflects the use of a common solution to the common need that all species have to interact with their chemical environment. The rather striking similarities seen in the organization of some of these chemosensory systems, especially olfaction, across a broad range of species suggest there is an optimal solution to the problem of detecting and discriminating chemosensory signals. Either this solution evolved relatively early and was subsequently retained or, more likely, different species convergently evolved the same or similar solutions to the chemosensory problem. As a result, the biological strategy for odor recognition, for example, should be worth emulating in designing biosensors to detect chemical compounds of importance in biomedicine, biosafety, and biodefense. Such biosensors need to detect multicomponent chemical signatures in the complex, dynamic chemical backgrounds that form real-world chemosensory environments. The utility of imitating this biological strategy to develop biosensors provides just one example of how one can learn from a broad, evolutionary approach to understanding chemical sensitivity.

The similarities seen between humans and other species in structural and functional elements of chemical sensing supports the continued use of animal models to investigate chemosensation. As noted by Dethier V. G. (1981), animal studies can tell us not only about those species but also about ourselves, provided we are careful to avoid the dual pitfalls of anthropomorphism and zoomorphism. Even knowing the extent to which chemical sensing in animals differs from that in humans cannot help but reveal something about ourselves.

Acknowledgments

B.W.A. gratefully acknowledges the contribution of his many students and postdoctoral associates over the years to the insight and ideas presented here. J.M.Y. thanks Barbara Trask and colleagues in the Trask laboratory for support, stimulating discussions, and explorations of the literature. The authors thank the National Institute of Deafness and Other Communication Disorders for support (DC05995 and DC04209). We also thank Ms M.L. Milstead for assistance with the illustrations and Ms J. Tulsian for assistance with the bibliography.

Glossary

adaptation The phenomenon of taste desensitization which occurs on iterative exposure to a taste stimulus over a short period of time, a phenomenon believed to be a consequence of receptor phosphorylation by kinases specific for action on G-protein-coupled receptors.

concentration/response function A function which describes the relationship between tastant response (R) and stimulus concentration (C). Generally, C/R functions take the form of the law of mass action $R = R_m C/(k_d + C)$, where R_m is maximal response and k_d is the apparent receptor/tastant dissociation constant.

epithelial sodium channel A multi-subunit ion channel protein, usually referred to as ENaC, believed to be the principal initiator in the activation of salt-sensitive taste bud cells.

flavor profile A graphical description of the quality of the taste of a stimulus in terms of the relative intensities of multiple sensory attributes such as sweet, bitter, umami, sour, and salty.

G-protein Heterotrimeric guanosine triphosphate (GTP)-binding proteins constituted of α, β, and γ subunits which transduce the activation of G-protein-coupled receptors into cellular activation.

G-protein-coupled receptor A membrane protein receptor, usually referred to as a GPCR, which signals the presence of an extracellular ligand to an intracellular signaling protein known as a G protein, thus leading to cellular activation. GPCRs are constituted of extracellular ligand-binding domains and intracellular G-protein-binding domains connected by seven α-helical transmembrane segments.

gustatory stimuli Chemical compounds which initiate responses from taste bud cells and are perceived as sweet, bitter, umami, sour, or salty in quality of taste.

inositol trisphosphate receptor A protein receptor, present on intracellular calcium storage vesicles in sweet-, bitter-, and umami-sensitive taste bud cells, which is activated by its ligand inositol trisphosphate (IP_3) to promote the release of calcium ions into the cytoplasm, free calcium being a key element in the cascade of reactions leading to cellular excitation.

phospholipase $C_{\beta 2}$ An enzyme present in sweet-, bitter-, and umami-sensitive taste bud cells which communicates receptor and G-protein activation by action on the membrane lipid phosphatidylinositol to produce inositol trisphosphate (IP_3) and diacylglycerol (DAG), where IP_3, and possibly DAG, are key elements in the cascade of reactions involved in excitation of taste bud cells.

polycystic-kidney-disease-like ion channel An ion channel protein of the transient receptor potential family thought to mediate the excitation of sour-sensitive taste bud cells.

T1R1/T1R3 The heterodimeric G-protein-coupled receptor constituted of the two proteins T1R1 and T1R3 which initiates the responses of umami-sensitive taste bud cells to monosodium glutamate and other savory stimulants.

T1R2/T1R3 The heterodimeric G-protein-coupled receptor constituted of the two proteins T1R2 and T1R3 which initiates the responses of sweet-sensitive taste bud cells to sweeteners.

T2R A member of the family of G-protein-coupled receptors (25 in humans) which initiates the responses of bitter-sensitive taste bud cells to bitterants.

temporal profile A graphical description of the temporal characteristics of a taste experience which includes quantification of the rate of taste onset and the rate of taste extinction.

transient receptor potential channel M5 An ion channel protein, usually referred to as TRPM5, which is activated by intracellular calcium and mediates the activation of sweet-, bitter-, and umami-sensitive taste bud cells through membrane depolarization.

transient receptor potential channel V1 An ion channel protein, usually referred to as TRPV1 and known to be the receptor for vanilloid trigeminal nerve stimulants including capsaicin, thought to work together with the epithelial sodium channel in excitation of salt-sensitive taste bud cells.

4.02.1 Introduction

All chemical compounds, whether organic, inorganic, or organometallic, exhibit taste and therefore are potential gustatory stimuli. This is a fundamental premise for the discussion to follow. In order to exhibit taste, however, compounds must be in solution and some compounds that appear to be tasteless are probably not really tasteless, but rather are insufficiently soluble to reach their thresholds for activation of any of the gustatory sensor systems. In this chapter, we undertake the challenge of developing a coherent picture of the relationship between chemical structure and biological activity for each of the common modalities of taste. Understanding the structure–activity relationship (SAR) within series of biologically active chemical compounds is the never-ending and elusive vision for medicinal, flavor and fragrance, and agricultural chemists. The reason for the elusive nature of this vision is made clear by a quotation of Melvin Calvin, 1961, Nobel laureate in chemistry:

> It's no trick to get the right answer when you have all the data. The real creative trick is to get the right answer when you have only half the data in hand and half of it is wrong. And you don't know which half.

Thus, as we challenge ourselves to understand the chemistry of gustatory stimuli, it is important to recognize that some of the data that we are trying to make sense out of are misleading at best and, in some cases, just wrong. With this fact in mind, we proceed.

What is taste? In the lexicon of the consumer, taste is the total sensory experience that results from a

superimposition of gustatory, olfactory, and chemesthetic sensory inputs to the central nervous system which occurs on sampling a food or beverage. And it can be argued that even the senses of vision and audition contribute significantly. In this Chapter, only gustatory stimuli are considered. Historically, it has been generally accepted that the sense of gustation is made up of the four modalities: sweet, bitter, sour, and salty. We now know that savory, often referred to by the Japanese word *umami*, is a fifth gustatory modality. In this Chapter, the relationship between chemical structure and gustatory activity, or gustatory SAR, for each of these five taste modalities is discussed. In each case, current understandings of the biochemical mechanisms are summarized first since without such a background, little sense can be made of SAR.

4.02.2 Sweet-Tasting Stimuli

Sweet taste is clearly a very important sensation as evidenced by the fact that wars have been fought and people enslaved over sugar, the prototypical sweet stimulus (Mintz, S. W., 1985). More sweeteners, principally sugar but also syrups derived from starch as well as a variety of noncaloric sweeteners, are added to foods and beverages than any other ingredient type. Human liking of sweet taste is innate as has been demonstrated by Steiner J. E. (1994). He studied the behavioral responses of newborns and clearly showed that they exhibit strong liking for sweettasting stimuli. As a consequence of the importance of sweet taste in the human diet, more research has been conducted on elucidating the biochemical pathways which mediate it and on the discovery and commercial development of noncaloric sweeteners than on bitter, umami, sour, and salty tastes combined. For this rationale, we discuss sweet-tasting stimuli first and in considerable detail.

4.02.2.1 Biochemistry of Sweet Taste

In spite of the importance of sweet taste to our daily enjoyment of life, until the late 1980s, the biochemical pathway which mediates it was largely unknown. Then, evidence began to accumulate that it must be G-protein-coupled receptor (GPCR) mediated. More specifically, sweet taste was thought to be the result of activation of several GPCRs since the findings of biochemical, electrophysiological, and psychophysical experiments could only be easily explained by a plurality of receptors (Faurion, A., 1987; DuBois, G. E., 1997). And this expectation was supported by the fact that multiple subtypes of GPCRs commonly exist for other important signal molecules (e.g., acetylcholine, norepinephrine, dopamine, serotonin, etc.).

In the early 2000s, a breakthrough occurred dramatically improving our understanding of sweet taste. In 2001, a collaborative team from the laboratories of Charles Zuker (University of California, San Diego) and Nicholas Ryba (US National Institutes of Health) reported the discovery of the rat sweetener receptor (Nelson, G. *et al.*, 2001). In a functional assay, they showed that all substances that rats generalize to sucrose taste appear to be mediated by a single receptor which their observations suggested to be a heterodimer of two 7-transmembrane domain (TMD) proteins which they named T1R2 and T1R3. This heterodimeric sweetener receptor is usually written as T1R2/T1R3. Both T1R2 and T1R3 are members of the small family of class C GPCRs. The most studied members of the class C GPCRs are the 8 homodimeric metabotrophic glutamate, single heterodimeric gamma-aminobutyric acid type B, and single homodimeric extracellular calcium receptors which have recently been reviewed (Pin, J.-P. *et al.*, 2003). This rat receptor discovery was quickly followed by the report by Li X. *et al.* (2002) of Senomyx (La Jolla, CA) of parallel findings for the human system. Again, as in the rodent, the results were most consistent with human sweet taste initiation by the single heterodimeric receptor T1R2/T1R3. Heterologous cells (i.e., HEK-293 cells), in which both human T1R2 and human T1R3 were expressed, responded to all structural types of sweeteners tested in a manner consistent with expectation from sensory experiments. Thus, at the present time, there is a general consensus that the heterodimer T1R2/T1R3 is the sweetener receptor. Evidence has been presented for the mouse by the Zuker and Ryba laboratories that a T1R3-only receptor, perhaps a homodimer, is functional as a carbohydrate (CHO)-only sweetener receptor (Zhao, G. Q. *et al.*, 2003). However, no evidence has yet been reported on such a receptor in humans or other animal models. At about the same time as the pioneering work by the Zuker and Ryba laboratories, several other laboratories also identified the T1R3 component of the receptor (Bachmanov, A. A. *et al.*, 2001; Max, M. *et al.*, 2001; Montmayeur, J.-P. *et al.*, 2001; Sainz, E. *et al.*, 2001).

Class C GPCRs are unique in that they possess very large N-terminal Venus flytrap-like domains (VFDs). For the case of the metabotrophic glutamate receptor mGluR1, Kunishima N. *et al.* (2000) demonstrated that its VFD closes on binding glutamate, hence the analogy to a Venus flytrap. This precedent, and the fact that the sweetener receptor and the umami receptor, shown in parallel work by Li and co-workers to be the GPCR heterodimer T1R1/T1R3, contain the common subunit T1R3 lead to the expectation that sweeteners likely bind in the VFD of T1R2. Subsequent work by Li and co-workers (Xu, H. *et al.*, 2004) probed the fundamental question of sweetener-binding locus with the finding that, while some sweeteners do bind in the VFD of T1R2 (e.g., aspartame and neotame), at least one sweetener (i.e., cyclamate) does not, but rather binds within the 7-TMD of T1R3. The binding of cyclamate to the TMD of T1R3 was corroborated by Robert Margolskee and associates of Mt Sinai School of Medicine (Jiang, P. *et al.*, 2005) with site-directed mutagenesis studies which provided significant detail on the interactions of cyclamate with T1R3. Other work by Margolskee and associates on brazzein, a natural protein sweetener, showed that its locus of binding is in the cysteine-rich domain (CRD) of T1R3, a subunit of the protein which connects VFD and TMD domains (Jiang, P. *et al.*, 2004). The human sweetener receptor is the first Class C GPCR demonstrated to have multiple agonist-binding loci (orthosteric sites).

A topic of considerable controversy in the field of taste research has been that of taste quality coding. Taste bud cells (TBCs) are known to be innervated by nerve fibers of three gustatory nerves: the chorda tympani (CT), the glossopharyngeal, and the superpetrosal nerves. Each of these nerves is a bundle of many individual fibers and some have argued that taste quality is coded by a cross-fiber pattern of activity and others have argued that individual fibers are specific for activity. Evidence for taste quality coding due to modality-specific fibers was provided by electrophysiological studies in chimpanzees by Goran Hellekant and Yuzo Ninomiya. They carried out single fiber recordings and demonstrated that some fibers responded only to sweeteners (Hellekant, G. and Ninomiya, Y., 1991) and other fibers responded only to bitterants (Hellekant, G. and Ninomiya, Y., 1994a; 1994b) leading them to conclude that taste quality is coded at the level of the TBC. In other words, they argued that individual TBCs are specific sensors for sweet, bitter, umami, sour, or salty. Further convincing evidence that taste quality coding occurs at the level of the TBC comes from recent work of the Zuker and Ryba laboratories. Early in 2003, working with $PLC_{\beta 2}$ knockout mice, they engineered mice in which they selectively rescued $PLC_{\beta 2}$ function in bitter receptor expressing cells (Zhang, Y. *et al.*, 2003) and found that these mice responded normally to bitterants but still exhibited no responses to sweet or umami stimuli. Later, working with T_1R knockout mice that gave no responses to sweet or umami stimuli, they engineered mice in which human T1R2 function was added to T1R3-expressing TBCs (Zhao, G. Q. *et al.*, 2003) and found that these mice responded to aspartame, a compound sweet to humans but inactive in mice. They also selectively introduced an opioid receptor into sweet-sensing TBCs and observed that these mice now responded with attraction to opioid agonists. In summary, the evidence is now strong that taste quality is coded at the level of the TBC.

The recent identification of the sweetener receptor and elucidation of the mechanism of sweet taste coding was preceded by the discovery of specific G proteins that mediate sweet taste. In 1992, Robert Margolskee, then at Roche Institute of Molecular Biology, and associates reported that a G protein closely related to transducin is critical for sweet taste (McLaughlin, S. K. *et al.*, 1992). They called this G-protein gustducin but noted that low levels of transducin are also present in TBCs. And, in addition, very recently, Guy Servant and co-workers (Senomyx) obtained evidence showing that the sweetener receptor can also functionally interact with $G_{\alpha i(o)}$ proteins (Ozeck, M. *et al.*, 2004). $G_{i(2)}$ is a favored $G_{\alpha i(o)}$ candidate as it was shown to be the most highly expressed $G_{\alpha i(o)}$ in TBCs. Other key elements of the sweet taste transduction cascade were identified by Margolskee and associates (Pérez, C. A. *et al.*, 2002) and by the Zuker and Ryba team (Zhang, Y. *et al.*, 2003). They found that phospholipase $C_{\beta 2}$ ($PLC_{\beta 2}$), the inositol trisphosphate (IP_3) receptor (IP_3R), and the transient receptor potential (TRP) channel m5 (TRPM5) are key effector elements in sweet taste transduction. Thus, at this time, evidence exists for the participation of one receptor (T1R2/T1R3), as many as three G proteins (gustducin, transducin, and possibly $G_{i(2)}$), one enzyme ($PLC_{\beta 2}$), a second messenger receptor (IP_3R), and an ion channel (TRPM5) in the activation of sweet-sensing TBCs. Recognition of (1) the relatively high concentrations of noncaloric sweeteners (i.e., millimolar levels) commonly employed in foods and beverages, (2) the fact that noncaloric

sweeteners are commonly lipophilic, and (3) the fact that such lipophilic molecules are generally absorbed into cells led to speculation (DuBois, G. E., 1997) that sweeteners may initiate their activity at intracellular elements of the transduction cascade. Support for this idea is provided by the work of Michael Naim and associates (Hebrew University) who reported that some noncaloric sweeteners have the capability to directly activate G proteins (Naim, M. *et al.*, 1994). And further support is provided by recent work from the Naim group through studies showing that several noncaloric sweeteners are rapidly taken up into TBCs (Zubare-Samuelov, M. *et al.*, 2005). However, in view of the finding that every sweetener tested by Senomyx investigators activated HEK-293 cells in which the T1R2/T1R3 receptor is expressed, while otherwise identical control cells, lacking only the T1R2/T1R3 receptor, are unaffected, it remains to be demonstrated that any sweeteners do actually act at downstream elements in the sweet-sensing TBC activation cascade. Further, since we now know that bitter and umami taste stimuli initiate their sensations at the TBC level through the same effectors which mediate sweet taste signaling (i.e., gustducin, $PLC_{\beta 2}$, IP_3R, and TRPM5), if any sweeteners do initiate their activities at intracellular components of TBCs, then they should also simultaneously activate bitter- and umami-sensitive TBCs resulting in mixed modality (i.e., sweet/bitter/umami) compounds. And while sweet/bitter compounds are known, no compounds with sweet/umami or sweet/bitter/umami taste have been reported, thus leading to the overall conclusion that initiation of sweet taste activity at intracellular targets of TBCs seems unlikely. Nonetheless, since Naim and co-workers have demonstrated that small molecules including some sweeteners are readily taken up into TBCs, it is logical to expect that some such compounds may exist.

In summary, transduction of sweet taste is generally accepted as proceeding via activation of the heterodimeric sweetener receptor T1R2/T1R3 with subsequent activation of the G protein gustducin (and/or transducin and possibly $G_{i(2)}$). In this generally accepted transduction pathway, the gustducin $G_\beta G_\gamma$ subunit activates $PLC_{\beta 2}$ to act on membrane phosphatidylinositol to produce IP_3, which acts at its receptor IP_3R on intracellular Ca^{2+} storage sites to release Ca^{2+}. And finally, Ca^{2+} gates the TRPM5 ion channel enabling the inward flow of Na^+, depolarizing the sweet-sensing TBC, and initiating signaling to the CNS. Evidence from the Zuker and Ryba laboratories argues that this gustducin $G_\beta G_\gamma$ pathway is the only sweet taste transduction pathway since mice in which the TRPM5 gene was partially deleted were observed to lack all behavioral and nerve responses to sweeteners (Zhang, Y. *et al.*, 2003). Earlier work, however, argues for a gustducin G_α pathway in sweet taste transduction, where G_α is the gustducin subunit which communicates with intracellular effectors (Varkevisser, B. and Kinnamon, S. C., 2000; Margolskee, R. F., 2002). And very recent work from the Margolskee laboratory (Damak, S. *et al.*, 2006), in which TRPM5 gene expression in the mouse was fully blocked, continues to argue for a sweet taste transduction pathway not mediated by TRPM5. In this work, the TRPM5 knockout mice continue to exhibit weak responses to sweeteners. And, in the electrophysiological component of this work, glossopharyngeal nerve responses were observed while the CT nerve responses were not, thus suggesting that transduction pathway may vary between TBCs innervated by the two different nerve systems. Thus, at this time, while we have a general consensus that the primary pathway for sweet taste transduction is the gustducin $G_\beta G_\gamma/PLC_{\beta 2}/IP_3R/$ TRPM5 pathway, it appears too early to conclude that it is the exclusive pathway.

4.02.2.2 Sweetener Structure–Activity Relationship

Since the early 1800s, chemists have discovered hundreds of synthetic and natural sweeteners and by the 1980s, at least 50 structural classes of sweet-tasting organic compounds were known. In an effort to make sense of this structural diversity, models were developed in an attempt to rationalize the relationship between structure and taste activity. These are pharmacophore models and the most well known of them is the so-called A-H/B model (Shallenberger, R. S. and Acree, T. E., 1967). In this model, it was hypothesized that all sweeteners contain H-bond donor and H-bond acceptor groups separated by not <2.5 or >4.0 Å. In effort to better explain empirical observations, many improved pharmacophore models have been developed since the A-H/B model (Kier, L. B., 1972; van der Heijden, A. *et al.*, 1985a; 1985b; Douglas, A. J. and Goodman, M. 1991; Rohse, H. and Belitz, H.-D., 1991; Temussi, P. A. *et al.*, 1991; Tinti, J.-M. and Nofre, C., 1991; Bassoli, A. *et al.*, 2002). An assumption implicit in all of these models is that sweetness is initiated following the binding of a sweetener to a single site

(i.e., orthosteric site) on a single receptor. However, recent studies on the mapping of sweetener-binding loci to the sweetener receptor (Jiang, P. *et al.*, 2004; Xu, H. *et al.*, 2004) have demonstrated that the human sweetener receptor contains at least three orthosteric sites and thus the A-H/B model as well as all of the other pharmacophore models, while perhaps correct within structural classes of sweeteners, are not correct in the general sense. In summary, it appears that human sweetness is substantially, and perhaps exclusively, initiated by activation of a single receptor, the GPCR heterodimer T1R2/T1R3, at a plurality (i.e., $\geq$3) of orthosteric sites. And therefore $\geq$3 pharmacophore models are required to characterize the relationship between chemical structure and sweet taste. The first model consistent with this logic was developed at The NutraSweet Company for the aspartame orthosteric site (Culberson, J. C. and Walters, D. E., 1991). Later, an enhancement of this aspartame pharmacophore model, employing comparative molecular field analysis to provide quantitative predictive power, was developed at The Coca-Cola Company (D'Angelo, L. and Iacobucci, G., 1995).

Over the last 200 years, chemists have identified and characterized many, many sweet-tasting chemical compounds. Many of these compounds are synthetic but also many of them have been found in nature. The most common sweeteners, present in ordinary fruits and vegetables, are CHO sweeteners. However, health concerns related to obesity and diabetes led to the commercial development of noncaloric sweeteners found either in the chemist's laboratory or in nature. In Sections 4.02.2.2.1–4.02.2.2.4 of this discussion on sweeteners is given a representative sampling of chemical compounds found to exhibit sweet taste. Numerous reviews on sweetener SAR are available (e.g., Lee, C.-K., 1987; Marie, S. and Piggott, J. R., 1991; Shallenberger, R. S., 1993; O'Brien Nabors, L., 2001; Kim, N.-C. and Kinghorn, A. D., 2002). In this review, all commercially developed sweeteners are discussed. Chemical structures, empirical formulas, molecular weights, and, to the extent available, sweetness potencies (P) are provided. In Section 4.02.2.2.5 of this section on sweet-tasting stimuli, important information on differences in sensory characteristics of sweeteners is presented. As explained, P values for CHO sweeteners are constants, independent of sucrose reference concentration, while for synthetic and natural noncaloric sweeteners, they are variable with a strong dependence on sucrose reference concentration. Thus, P values for synthetic and natural noncaloric sweeteners are given relative to a sucrose reference and are on a weight basis (P_w). P_w values can easily be converted to molar basis potencies (P_m) by multiplication by the factor $M_{compound}/M_{sucrose}$ (i.e., the ratio of the molecular weights of a compound and of sucrose). Sweetness potencies for the synthetic and natural noncaloric sweeteners are expressed as $P_w(X)$ where X is the sucrose reference concentration (% w/v). Ideally, all P_w values would be provided relative to a common sucrose reference, determined by a common protocol and be at a sucrose use level relevant to food and beverage applications (e.g., 10% sucrose). However, synthetic and natural noncaloric sweeteners have variable maximal responses that in many cases are much less than 10% sucrose sweetness equivalency. And oftentimes, literature sweetness potencies are reported without sucrose reference information. Such unreferenced sweetness potencies are reported here as P_w(ur). As a consequence of these and other complexities, the comparison of sweetness potencies for sweeteners reported by different authors using different protocols is difficult at best.

4.02.2.2.1 Carbohydrate caloric, partially caloric and noncaloric sweeteners

CHOs are generally considered to be aldehyde- or ketone-containing polyhydroxylic compounds which most commonly exist in hemiacetal, acetal, hemiketal, or ketal forms. In nature, CHOs exist predominantly in polymeric form. Principal among the natural CHO polymers are starch and cellulose, both of which are glucose polymers, and chitin, a polymer of 2-acetamido-2-deoxyglucose. Polymeric CHOs are not sweet. At the same time, all low molecular weight CHOs are sweet-tasting compounds. Some low molecular weight CHOs are also bitter, but all are sweet with P_w values within a factor of 0.1–2 of that of sucrose. In the author's (GED) experience, reports in the literature to the contrary are incorrect. The most common of the CHO sweeteners is sucrose, a disaccharide constituted of glucose and fructose monosaccharide subunits. Sucrose is produced on a very large scale with 2005 world production forecast at 144.8×10^6 MT. In acidic foods and beverages, sucrose hydrolyzes to a 1/1 mixture of glucose and fructose as illustrated in Figure 1. This 1/1 glucose/fructose mixture is prepared on a commercial scale from sucrose and is called invert sugar. Other glucose/fructose mixtures are manufactured from starch on a very large scale. These products are known as high fructose starch syrups (HFSSs) and are available as

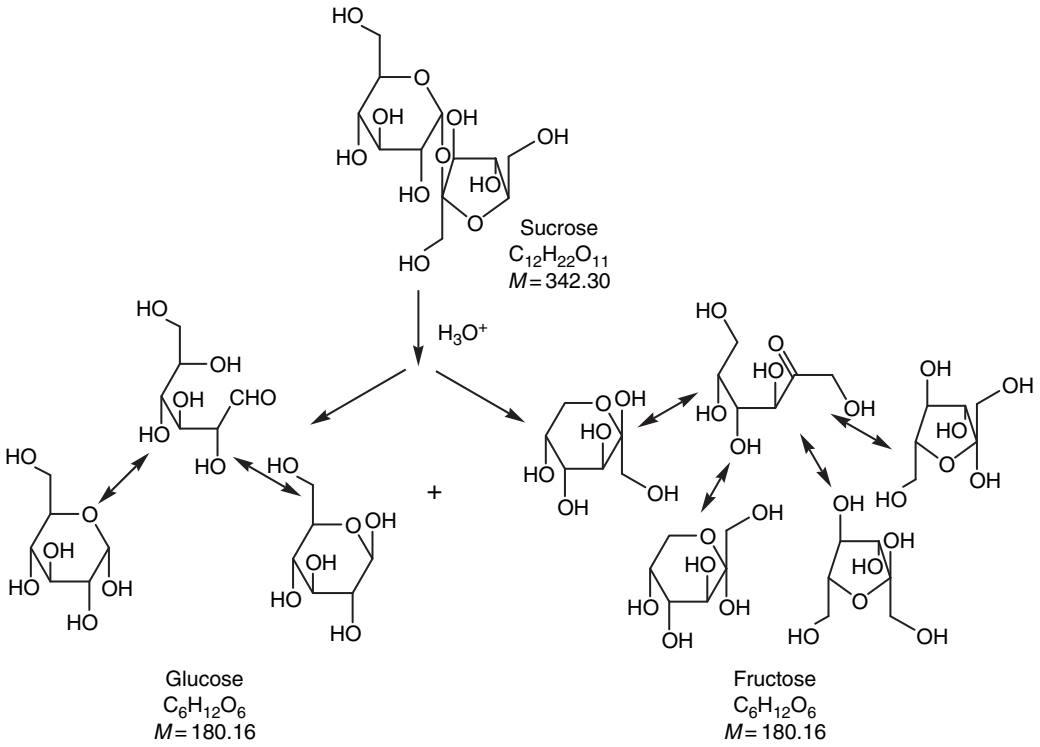

Figure 1 The hydrolysis of sucrose to glucose and fructose.

42% fructose (HFSS-42), 55% fructose (HFSS-55), and 90% fructose (HFSS-90). It is important to recognize that, while sucrose is a single chemical entity, glucose is a mixture of three tautomeric forms and fructose, a mixture of five tautomeric forms, the tautomeric forms of each monosaccharide being in rapid equilibrium with each other. And thus, in acidic foods or beverages sweetened with sucrose, the active sweetener system is a mixture of three compounds, with two of them present in eight tautomeric forms, all present simultaneously. Efforts have been made to determine the relative sweetness potencies of the different tautomeric forms of glucose and fructose. However, since these tautomers are in rapid equilibrium, the published sweetness potencies are highly speculative.

A great many other low molecular weight CHOs are known and all are sweet to humans. A sampling of mono-, di-, and oligosaccharides, intended to illustrate the diversity of sweet-tasting CHOs, is provided in Figures 2 and 3 along with their sweetness potencies where available. No attempt has been made to be comprehensive in this listing. The examples given are provided simply to illustrate the breadth of the SAR among CHO sweeteners. Some low molecular weight CHOs are reported to be bitter rather than sweet. As example, gentiobiose is reported to be bitter (Pfeilsticker, K. *et al.*, 1978). However, as a 25% solution, a commercial sample was observed to exhibit both sweet and bitter tastes (DuBois, G. E. *et al.*, 1994). In work on synthetic analogs of natural CHOs, many of them, even at high states of purity, exhibit bitterness (DuBois, G. E., 1997). However, in general, further purification resulted in purely sweet samples. It seems likely that the bitter tastes reported for many CHOs may be due to potent bitter contaminants.

The simplest monosaccharide CHOs, glycolaldehyde (**1**) and glyceraldehyde (**2**), cannot form monomeric cyclic acetals or ketals and are reported to exist primarily in dimeric form and thus their active pharmacophores are believed to be their dimeric hemiacetals. All of the higher molecular weight monosaccharide CHOs illustrated exist almost exclusively as cyclic hemiacetal or hemiketal tautomeric forms. And thus it is believed that their active pharmacophores are the cyclic tautomers. A very surprising finding among the monosaccharide CHOs is the total absence of enantiospecificity in some enantiomeric pairs. Thus Shallenberger R. S. *et al.* (1969) reported complete inability of human

subjects to differentiate D- and L-enantiomers for several sugars. Birch G. G. *et al.* (1996) corroborated the Shallenberger report for the case of D- and L-arabinose, **5** and **6**. And the author (GED) and Singer N. (1984) corroborated the Shallenberger report for the case of D- and L-glucose, **7** and **8**. In both the arabinose and the glucose enantiomeric pairs, identical tastes are observed when tasted at equal concentrations. In contrast, however, D- and L-fructose are quite different, with the natural D enantiomer being approximately twice as potent as the L enantiomer (DuBois, G. E., 1995). Given that CHO sweeteners are thought to activate the sweetener receptor T1R2/T1R3 through a binding interaction, it is to be expected that enantiomers should differ in their binding effectiveness and thus the observed difference in potencies for the fructose enantiomers is expected. However, identical sweetness potencies within the D/L arabinose and D/L glucose enantiomeric pairs are very surprising.

It seems very unlikely that each enantiomer in a pair of CHO sweeteners should bind with equal affinity to the receptor and this reasoning led to the suggestion that CHOs as well as other highly hydrophilic compounds may activate the receptor via a nonbinding mechanism (DuBois, G. E., 1997). The binding sites for the natural agonists for family C GPCRs are known to be in the VFDs

and these agonists are believed to activate the receptor by causing the VFD to adopt a closed conformation. And recent work on an analog of the $GABA_B$ family C GPCR, engineered to exist exclusively in a closed conformation (Kniazeff, J. *et al* 2004), shows that the closed conformation is fully active. The binding site for aspartame has been shown to be in the VFD of the T1R2 component of the T1R2/T1R3 receptor (Xu, H. *et al*., 2004) and recent evidence (Nie, Y. *et al*., 2005) suggests that sucrose binds in the VFDs of both T1R2 and T1R3. Thus, it appears that CHO sweeteners most likely modulate the equilibrium between the open (inactive) and closed (active) conformations of the VFD of T1R2 and perhaps T1R3 as well. If this is the case, it seems reasonable that the open/closed equilibria could be altered in two ways. The first possibility is that CHO sweeteners, like other family C GPCR agonists, bind to a site within the VFD. A second possibility, however, is that CHO sweeteners activate the receptor by a nonbinding mechanism where they simply alter the VFD open/closed equilibrium in favor of the closed conformation by a general solvent effect. Solution equilibria of all types are well known to be solvent dependent and a change in the open/closed equilibria for T1R2 and T1R3 to favor the closed forms that is promoted by a change in solvent from normal saliva to a concentrated CHO sweetener solution should not be a surprise. Thus, it could well be that CHO sweeteners showing no enantiospecificity (i.e., D/L arabinose and D/L glucose) may activate the receptor exclusively by a nonbinding mechanism and that CHO sweeteners which do show enantiospecificity (i.e., D/L fructose) activate the receptor by both binding and nonbinding mechanisms. If this nonbinding pathway for sweetener receptor activation does exist, then it is to be expected that all sweeteners acting by this pathway should exhibit similar levels of activity. And they do, as is made clear with the examples to follow.

The aldehyde or ketone moieties present in the CHO sweeteners in Figure 2 are not prerequisites for sweet taste. Simple alcohols as well as CHO reduction products, often referred to as polyols, are also sweet in taste. An exemplary list of polyol sweeteners is provided in Figure 4.

Within the last 20–30 years, due to the increased interest in reduced-calorie food and beverage products, substantial interest has been expended on the commercial development of reduced-calorie CHOs and polyols. Among naturally occurring CHOs and polyols already mentioned which are reduced in bioavailable energy content are the naturally occurring *meso*-erythritol and D-tagatose. In the United States, the FDA has accepted bioavailable calorie levels of 0.2 and 1.5 kcal g^{-1} for erythritol and D-tagatose, respectively, although, in Japan, an energy content for erythritol of 0.0 kcal g^{-1} is accepted. A number of semisynthetic reduced-calorie CHOs and polyols have been commercially developed. These compounds are listed in Figure 5.

A survey of the relationship between structure and activity for the CHO sweeteners shown above leads to the expectation that any polyhydroxylic organic compound may be sweet. In food applications, sucrose, the most common CHO sweetener, provides functionality beyond sweetness including freezing point depression (frozen desserts) and starch gelatinization point elevation (baked goods). These properties are colligative in nature and thus the ideal noncaloric CHO sweetener should have molecular weight comparable to that of sucrose. In addition, the quality of taste of CHO sweeteners was noted to be dependent on the ratio of hydroxyl groups to carbon atoms. This logic led the author (GED) and a team at The NutraSweet Company to the synthesis of a diverse group of approximately 100 CHO-like noncaloric sweeteners (DuBois, G. E. *et al*., 1992). Compounds **35–38**, illustrated in Figure 6, are exemplary of this work and all are noncaloric and exhibit clean sweet tastes. At about the same time, Adam Mazur and co-workers (Procter & Gamble Company) reported the synthetic lactitol derivative **39** to be sweet and noncaloric.

4.02.2.2.2 Synthetic noncaloric sweeteners

The field of organic chemistry really had its beginning in the nineteenth century. Many new chemical reactions were discovered and novel chemicals synthesized. These new chemical compounds were characterized by techniques available at the time which included physical description (i.e., solid, liquid, crystalline form, etc.), color, boiling point, melting point, odor, and, of particular reference to this discussion, taste. The routine tasting of novel chemical compounds by chemists continued well into the twentieth century. And in this way, synthetic sweeteners were discovered among many structural classes of compounds. Examples of 21 structural classes of synthetic noncaloric sweeteners, along with chemical structures, molecular weights,

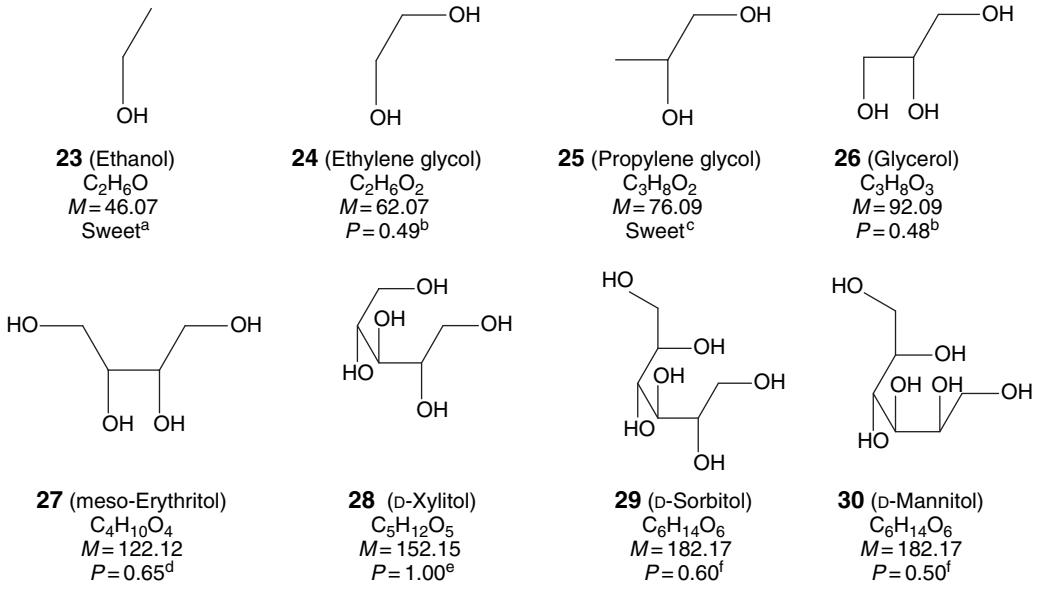

Figure 4 Examples of common polyol sweeteners. [a]Scinska A. *et al*. (2000); [b]Shallenberger R. S. (1993); [c,d]Embuscado M. E. and Patil S. K. (2001); [e]Olinger P. M. and Pepper T. (2001); and [f]Le A. S. and Bowe Mulderrig K. (2001).

empirical formulas, and sweetness potency information, are provided in Figures 7 and 8. Generic and common names are provided for sweeteners which have been commercially developed. The sweeteners are listed in the approximate order of their discovery. Additional information on the discoveries of each of these classes of sweeteners is as follows:

1. *Nitroanilines.* Muspratt J. and Hofmann A. (1846) reported sweet taste for *m*-nitroaniline (**40**) and this is the earliest report, of which the author (GED) is aware, of a compound more potent than common CHO sweeteners. Nearly a century later, the very potent analog P-4000 (**41**) was reported by Blanksma J. J. and van der Weyden P. W. M. (1940) of the Rijks-Universiteit (Leiden, The Netherlands). For many years, P-4000 was the most potent sweetener known.
2. *N-Sulfonyl amides.* Saccharin (**42**) is the first sweetener of this structural type. The sweetness of saccharin was discovered by Constantine Fahlberg in the laboratory of Ira Remsen at Johns Hopkins University (Fahlberg, C. and Remsen, I., 1879) and was commercialized in the United States as the first product of the Monsanto Chemical Company. Much

later, the structurally similar oxathiazinone class of sweeteners was discovered by chemists Clauss K. and Jensen H. (1973) of Hoechst AG and acesulfame (**43**) selected for commercial development. Both saccharin (Na and Ca salts) and acesulfame (K salt) have broad approvals for use in foods and beverages. Also, both sweeteners exhibit significant bitter/metallic off tastes and, for this reason, are almost always blended with other sweeteners.

3. *Aryl ureas.* Berlinerblau J. (1883), in the laboratory of R. Schmitt of Polytechnikum Dresden (Germany), reported the discovery of a series of sweet-tasting aryl ureas. Dulcin (**44**) is the best representative of this structural class of sweeteners which is the third structural class of synthetic sweeteners to be reported. Dulcin was evaluated as a candidate for commercial development but, following the finding of significant toxicity in rat studies at 0.1% of the diet, was not further considered (Fitzhugh, O. G. *et al.*, 1951).
4. *Oximes.* Many oximes have been found to be sweet. The first example was reported by Furukawa S. and Tomizawa Z. (1920). This compound is the oxime (**45**) of perillaldehyde. It was reported to exhibit a sweetness potency of 3400 relative to 9% glucose. Since glucose is 0.6× sucrose in sweetness potency, its sucrose basis sweetness potency is calculated to be $P_w(5.4) = 3400$.

(1965); [d]Suarez T. *et al*. (1975); [e]Hofmann A. (1972); [f]Lapidus M. and Sweeney M. (1973); [g]Hough L. and Phadnis S. P. (1976); [h]Tinti J.-M. and Nofre C. (1991); [i]Gries H. and Mützel W. (1985); [j]Nofre C. *et al.* (1990); and [k]Nagarajan S. *et al.* (1992).

reported that members of this structural class of compounds show very sweet taste. Exemplary is 2-carboxyethylbenzimidazole (**46**).

6. *Hydrazides*. Simple carboxylic acid hydrazides were discovered to be sweet in taste by DeGraaf H. (1930). Exemplary is the dihydrazide derivative of succinic acid (**47**).
7. *Sulfamates*. The discovery of sweet taste in this structural type of compounds was made by Michael Sveda in the laboratory of Professor L.

Audrieth at the University of Illinois (Audrieth, L. F. and Sveda, M., 1944). The best known sweetener of this structural class is *N*-cyclohexylsulfamic acid (**48**), commercially developed in the sodium and calcium salt forms which are well known as cyclamates. Cyclamates have been widely used in foods and beverages, usually in blends with other noncaloric sweeteners.

8. *Carboxyalkyl aryl ureas*. The discovery of sweet taste in this class of compounds was reported by Petersen S. and Müller E. (1948) of Farbenfabriken Bayer (Leverkusen, Germany). Later, a substantial number of sweet analogs were reported by Tinti J.-M. *et al.* (1982) of the Université Claude Bernard (Lyon, France).
9. *β-Amino cinnamonitriles*. Dornow A. *et al.* (1949) of Institut für Organische Chemie der Technischen Hochschule (Hanover, Germany) reported this structural class of sweeteners which is best exemplified by **50**.
10. *Carboxy benzophenones*. Runti C. and Galimberti S. (1957) of the University of Trieste reported this structural class of sweeteners which is best exemplified by **51**.
11. *Halogenated malonamides*. Runti C. and Collino F. (1964) of the University of Trieste reported this structural class of sweeteners which is best exemplified by **52**.
12. *Dipeptide esters and amides*. This is the structural class of noncaloric sweeteners of greatest commercial significance and is best exemplified by aspartame (**53**). The sweet taste of aspartame was serendipitously discovered in 1965 by James Schlatter in the laboratory of Robert Mazur of Searle Pharmaceutical Company (Mazur, R. H. *et al.*, 1969). Aspartame is unique among synthetic sweeteners as its metabolism leads only to natural amino acids and methanol, all of which are ingested in much higher amounts on consumption of common foods. Neotame (**54**), an analog of aspartame with substantially increased potency, was reported recently by Nofre C. and Tinti J.-M. (2000) of the Université Claude Bernard. It has also been commercially developed. Many dipeptide class sweeteners have been identified since the pioneering work by Mazur and co-workers. Included among such discoveries are the related dipeptide amides, exemplified by alitame (**55**) by Brennan T. M. and Hendrick M. E. (1983) of Pfizer Pharmaceutical Company, and **56** by Sweeny J. G. *et al.* (1995) of The Coca-Cola Company. Alitame has also been commercially developed.
13. *Dihydrochalcones*. Horowitz R. M. and Gentili B. (1969), of the USDA Laboratory (Pasadena, CA), reported the discovery of a series of sweet-tasting dihydrochalcones. The discovery of sweet taste in this series of compounds was particularly unexpected since it was made in a study of bitter taste SAR within flavanoid glycosides which are well known to exhibit potent bitterness. Neohesperidin dihydrochalcone (**57**), the preferred compound in the series, has been commercially developed but has only seen limited use because of sweetness which is noticeably delayed in onset and which lingers very significantly.
14. *Sulfones*. The discovery of sweet taste in this class of compounds, exemplified by **58**, was made by Aleksander Ratajczak in the laboratory of Donald Cram at UCLA (Cram, D. J. and Ratajczak, A., 1971). This class of sweeteners has been described in detail by Polanski J. and Ratajczak A. (1993).
15. *Pyrimidines*. The discovery of potent sweet taste among substituted pyrimidines, exemplified by **59**, was reported by Budesinsky Z. and Vavrina J. of the Research Institute for Pharmacy and Biochemistry (Prague, Czechoslovakia) in 1972.
16. *D-Amino acids*. Many D-amino acids are sweet with the most potent being D-tryptophan (**60**) (Solms, J. *et al.*, 1965). Much more potent substituted analogs were reported by Suarez T. *et al.* (1975) of Eli Lilly Pharmaceutical Company including **61**. And, at about the same time, in a study of lysergic acid derivatives by Hofmann A. (1972) of Sandoz AG (Basel, Switzerland), **62** was reported to be twice as sweet as saccharin.
17. *N′-Acyl-aspartyl-anilides*. The discovery of this structural class of sweeteners, exemplified by **63**, which is clearly related to the carboxyalkyl aryl ureas, was reported by Lapidus M. and Sweeney M. (1973) of Wyeth Laboratories (Philadelphia, PA).
18. *Halogenated sugars*. The discovery of substantial elevation in sweetness potency of sucrose by halogen substitution of sugar hydroxyl groups was first reported by Hough L. and Phadnis S. P. (1976) of the University of London. The most well-known member of this structural class is sucralose (**64**) which has been commercially developed.
19. *Dipeptide ester/carboxyalkyl aryl urea hybrids*. Tinti J.-M. and Nofre C. (1991) of Université Claude Bernard (Lyon, France) reported the discovery

of highly potent hybrids of the dipeptide ester and carboxyalkyl aryl urea classes of sweeteners. Exemplary of such hybrid sweeteners is a compound that they named superaspartame (**65**). This finding strongly suggests that these two classes of sweeteners bind to the sweetener receptor at contiguous and overlapping sites.

20. *Halogenated carboxyalkyl benzamides*. Gries H. and Mützel W. (1985) of Schering Pharmaceutical Company AG (Berlin, Germany) reported the discovery of a highly potent class of substituted benzamides best exemplified by **66**.
21. *Guanidinoacetic acids*. In the mid-1980s, based on modeling made possible by their superaspartame discovery, Nofre C. *et al.* (1990) of the Université Claude Bernard (Lyon, France) discovered the guanidino-acetic acid class of sweeteners. This class is exemplified by SC-45647 (**67**) which has proven useful in mechanistic studies of sweet taste because of its activity in common animal models. It is further exemplified by the more potent sucrononic acid (**68**), also discovered by Nofre and co-workers and **69** discovered by Nagarajan S. *et al.* (1996) of The NutraSweet Company who were in collaboration with the Université Claude Bernard team.

4.02.2.2.3 Natural noncaloric sweeteners

As organic chemists discovered sweet taste in many novel synthetic compounds, they also elucidated the chemical structures of many sweet-tasting compounds found in nature. Natural product structure elucidation was a very difficult process up until the second half of the twentieth century. Although in very significant part, the difficulty in structure elucidation of natural noncaloric sweeteners was due to their structural complexity, the difficulty was also due to the absence of modern spectroscopic and chromatographic methods that now make such structure elucidations routine. What was impossible, or a very challenging task 50 years ago, can now usually be accomplished within a few days. Examples of noncaloric sweeteners found in nature are illustrated in Figures 9–12. Two research groups in particular have been active, beginning in the mid-1970s and continuing up until the mid-1990s, in the elucidation of the structures of natural noncaloric sweeteners. One was an American group led by A. Douglas Kinghorn of the University of Illinois at Chicago. And the second was a Japanese group led by Osamu Tanaka of Hiroshima University. Both groups made major contributions to our understanding of the diversity of potently sweet chemical compounds which exist in nature. The increase in structural complexity between the natural noncaloric sweeteners discussed here and the synthetic noncaloric sweeteners discussed above is noteworthy. A high percentage of the natural noncaloric sweeteners are glycosylated terpenoids or flavanoids, many times with unusual sugars, and still others are proteins. As a result of this structural complexity, economical preparation of natural noncaloric sweeteners by synthetic methods is quite unlikely. Examples of 21 structural classes of natural noncaloric sweeteners along with chemical structures, molecular weights, empirical formulas, and sweetness potency information are provided in Figures 9–12. Information on six protein sweeteners is provided below without structure. Common names are used for sweeteners which have been commercially developed or which, for other reasons, are best known by such names. The sweeteners are listed according to structural class (i.e., terpenoids, flavanoids, etc.). Additional information on the discoveries of each of these natural noncaloric sweeteners is as follows:

1. *Hernandulcin (**70**)*. The only nonglycosylated sweet-tasting sesquiterpenoid identified in nature to date is hernandulcin. Kinghorn and associates (Compadre, C. M. *et al.*, 1987) reported the isolation of hernandulcin from the Mexican plant *Lippia dulcis* Trev. (Verbenaceae).
2. *Pine rosin diterpenoid (**71**)*. One sweet-tasting nonglycosylated diterpenoid natural product has also been reported. Tahara A. *et al.* (1971) of The Institute of Physical and Chemical Research (Saitama-ken, Japan) reported elucidation of the structure of **71**, a potently sweet compound present in pine tree rosin.
3. *Mukuroziosides (**72**)*. A glycosylated sesquiterpenoid exhibiting sweet taste was first identified in *Sapindus mukurossi* Gaertn. (Sapindaceae) by Tanaka and co-workers (Kasai, R. *et al.*, 1986). It is present at high levels in the fruits of this plant and is responsible for its sweetness.
4. *Stevioside (**73**) and rebaudioside A (**74**)*. A total of eight sweet-tasting glycosides of an entkaurene-type diterpenoid known as steviol have been isolated from the plant *Stevia rebaudiana* (Bertoni), indigenous to Paraguay. In the common variety of the plant, stevioside is the most abundant, and rebaudioside A, the second most abundant, steviol glycoside. Several groups have participated in elucidation of the structures of the steviol glycosides

Figure 10 Triterpenoid natural noncaloric sweeteners. [a]DuBois G. E. (2000); [b]Hashimoto Y. *et al.* (1980); [c]Nishizawa M. and Yamada H. (1996); [d]Kim J. *et al.* (1988); [e]Kasai R. *et al.* (1989); [f]Choi Y.-H. *et al.* (1989); [g]Shu R. G. *et al.* (1995); and [h]Kennelly E. J. *et al.* (1995).

Glycyrrhizic acid is commercially available as the monoammonium salt and is characterized as exhibiting sweetness with a notable delay in onset and with a long linger. Glycyrrhizic acid and its salts have approval for use as flavors in the United States.

7. *Periandrin I (**78**).* The structure elucidation of the sweet-tasting triterpenoid glycosides known as the periandrins I–IV, isolated from the Brazilian plant *Periandra dulcis* Mart. (Leguminosae), was completed by Hashimoto Y. *et al.* (1980) of Kobe Women's College of Pharmacy in the early 1980s. The taste properties of the periandrins are similar to those of glycyrrhizic acid.
8. *Osladin (**79**).* The structure elucidation of the sweet-tasting triterpenoid glycoside known as osladin, isolated from the rhizomes of the fern *Polypodium vulgare* L. (Polypodiaceae), was only completed recently following an X-ray crystal structure determination by Nishizawa M. and Yamada H. (1996).
9. *Polypodoside A (**80**).* The structure elucidation of the sweet-tasting triterpenoid glycosides polypodosides A and B isolated from the North American fern *Polypodium glycyrrhiza* DC. Eaton (Polypodiaceae) was completed by Kinghorn and co-workers (Kim, J. *et al.*, 1988).
10. *Mogroside V (**81**).* The structure elucidation of the sweet-tasting cucurbitane-type triterpenoid glycosides mogrosides IV and V isolated from the Chinese medicinal plant known as Luo Han Guo (*Siraitia grosvenorii* (Swingle) C. Jeffrey) was completed by Tanaka and co-workers in the late 1980s (Kasai, R. *et al.*, 1989; Matsumoto, K. *et al.*, 1990). Extracts of this plant are in common use in China and recently, a concentrate from the fruit of this plant has been commercially developed by Procter & Gamble for use in formulation of reduced-calorie beverages.
11. *Abrusoside A (**82**).* The structure elucidation of the sweet-tasting cycloartenol-type triterpenoid glycoside abrusoside A isolated from *Abrus precatorius* L. (Leguminosae) was completed by Kinghorn and co-workers (Choi, Y.-H. *et al.*, 1989).
12. *Cyclocarioside I (**83**).* The structure elucidation of the sweet-tasting dammarane-type triterpenoid glycoside cyclocarioside I, isolated from the leaves of the Chinese plant *Cyclocarya paliurus* Batal. Iljinsk (Juglandaceae) was completed by Shu R. G. *et al.* (1995) of Jiangxi College of Traditional Chinese Medicine. This plant is said to be used in China for the treatment of diabetes.
13. *Pterocaryoside A (**84**).* The structure elucidation of the sweet-tasting secodammarane-type triterpenoid glycosides pterocaryosides A and B, isolated from the leaves of *Pterocarya paliurus* Batal. (Juglandaceae) was reported by Kinghorn and co-workers (Kennelly, E. J. *et al.*, 1995). The leaves of this plant are used in China to sweeten foods.

14. *Phyllodulcin (85).* The structure elucidation of the sweet-tasting 3,4-dihydroisocoumarin-type polyketide isolated from the leaves of *Hydrangea macrophylla* Seringe var. *thunbergii* (Siebold) Makino (Saxifragaceae) was completed by Arakawa H. and Nakazaki M. (1959) of Osaka City University. Extracts of the leaves of this plant are used in Japan to make a sweet tea at a festival known as Hamatsuri, a celebration of Buddha's birth.
15. *Phloridzin (86).* The sweet-tasting dihydrochalcone glycoside phloridzin is present in many parts of apple trees except for the mature fruit. Its structure was elucidated and first isolated from the leaves of *Symplocos lancitolia* Sieb. by Tanaka T. *et al.* (1982).
16. *Neoastilbin (87).* The flavanone glycoside neoastilbin is reported to be the sweet-tasting component in the leaves of *Engelhardtia chrysolepis* Hance (Juglandaceae), a tree which grows in a subtropical region of China. Its structure was elucidated by Tanaka and co-workers (Kasai, R. *et al.*, 1988).
17. *[2(R),3(R)]-Dihydroquercetin-3-O-acetate (88).* The structure elucidation of this sweet-tasting flavanone, isolated from *Tessaria dodoneifolia* (Hook

and Arn.) Cabrera (Compositae), a plant indigenous to Paraguay, was reported by Kinghorn and co-workers (Nanayakkara, N. P. D. *et al.*, 1988).

18. *Cinnamaldehyde (**89**).* *trans*-Cinnamaldehyde was identified as the sweet-tasting component in *Cinnamomum osmophloeum* Kanehira (Lauraceae) by Kinghorn and co-workers (Hussain, R. A. *et al.*, 1990).
19. *Selligueain A (**90**).* The structure elucidation of the sweet-tasting proanthocyanidin selligueain A, following isolation from the rhizomes of the Indonesian fern *Selliguea feei* Bory (Polypodiaceae), was reported by Kinghorn and co-workers (Baek, N.-I. *et al.*, 1993).
20. *Hematoxylin (**91**).* The benzo[*b*]indeno[1,2-*d*]pyran hematoxylin is reported to be the sweet-tasting component in an extract of the heartwood of *Haematoxylon campechianum* L. (Leguminosaeae). Its structure was elucidated by Tanaka and co-workers (Masuda, H. *et al.*, 1991). This compound had been used as a microbiological staining agent but was not previously recognized to be sweet.
21. *Monatin (**92**).* The sweet-tasting amino acid monatin was isolated from the roots of the African plant *Schlerochiton ilicifolius* A. Meeuse (Acanthaceae). The structure of monatin was reported by Louis Ackerman and co-workers of the University of Pretoria (Pretoria, South Africa) (Vleggaar, R. *et al.*, 1992). In later work by Bassoli A. *et al.* (2005) of the University of Milan, it was found that all four stereoisomers are present in an extract

of the natural source, that all four stereoisomers exhibit sweetness, but that the most potent stereoisomer is the 2*R*/4*R* form.

22. *Thaumatin (93).* The sweet-tasting component in the berries of the West African plant *Thaumatococcus danielli* Benth, locally known as katempfe berries, was first isolated by van der Wel H. (1972) at Unilever and shown to be a protein. This protein called thaumatin was later shown to be a mixture of at least four similar 207 amino acid proteins. Thaumatin I, one of the two major forms, has $M = 22\,206$. The crystal structure of thaumatin was determined by Sung-Hou Kim and co-workers at the University of California at Berkeley (de Vos, A. M. *et al.*, 1985). Thaumatin exhibits potent sweetness [$P_w(10) = 1600$] with a notable delay in onset and with a very pronounced sweetness linger (DuBois, G. E., 2000).
23. *Monellin (94).* The sweet-tasting component in the berries of the West African plant *Dioscoreophyllum cumminsii*, also known as the serendipity berry, was first isolated by Morris J. A. and Cagan R. H. (1972) at Monell Chemical Senses Center and shown to be a protein. Monellin consists of two separate peptide chains, the A chain of 45 and the B chain of 50 amino acid residues, which are associated noncovalently with each other and has $M = 11\,086$. And the crystal structure was determined by Sung-Hou Kim and co-workers at the University of California at Berkeley (Ogata, C. *et al.*, 1987). Like thaumatin, monellin exhibits potent sweetness [$P_w(\text{ur}) = 3000$] with a notable delay in onset and with a very pronounced sweetness linger.
24. *Mabinlin (95).* The sweet-tasting component in the seeds of the Chinese plant *Capparis masaikai* Levl. (Capparidaceae) was shown to be a mixture of two proteins known as mabinlins I and II. In work by Masanori Kohmura and Yasuo Ariyoshi of Ajinomoto Company (1998), mabinlin II was determined to be composed of an A chain (33 amino acids) and a B chain (72 amino acids) which are connected via disulfide linkages. It was determined to have $M = 12\,441$ and sweetness recognition threshold of 0.1%. Since the threshold for sucrose sweetness recognition is *c.* 0.5%, it is only slightly more potent than sucrose.
25. *Brazzein (96).* The sweet-tasting component in the fruits of the African climbing vine *Pentadiplandra brazzeana* Baillon (Pentadiplandraceae) was demonstrated by Ming D. and Hellekant G. (1994) of the University of Wisconsin to be a 54 amino acid residue protein with $M = 6473$ and $P_w(2) = 2000$.
26. *Miraculin (97).* A protein isolated from the fruits of the African plant *Richardella dulcifica* (Schum. et Thonn.) Baehni (Sapotaceae), often referred to as miracle fruit, is known as miraculin and was first shown to be a protein by Kurihara K. and Beidler L. (1968) of Florida State University. This protein, having $M = c.\ 24\,000$, is not sweet at all but, interestingly, causes sour solutions to taste sweet.
27. *Curculin (98).* The sweet-tasting component in the fruit of the Malaysian plant *Curculigo latifolia* was shown by Yoshie Kurihara and co-workers of Yokohama University to be a dimer of a 114 amino acid polypeptide ($M = 24\,734$) (Yamashita, H. *et al.*, 1990). They named this protein curculin. Curculin, in addition to being a sweetener, causes sour solutions to taste sweet and also causes water to taste sweet. Curculin exhibits $P_w(6.8) = 550$.

4.02.2.2.4 Sweet-tasting minerals

Sweet taste is not limited to organic chemicals. Many inorganic salts are also known to exhibit sweet taste. Since the late 1800s, there have been many reports of sweet taste among inorganic salts and this topic has been reviewed by Shallenberger R. S. (1993). Sweet taste has been generally reported for alkali metal salts. As example, for NaCl, von Skramlik E. reported (1926) that its taste changes from tasteless at 9 mM, to slightly sweet at 10 mM, to sweet at 20 mM, to strongly sweet at 30 mM, to salty sweet at 40 mM to salty at 50 mM. In more recent work on the sweet taste of NaCl, Bartoshuk L. M. *et al.* (1978) of Yale University confirmed the presence of sweet taste but found that its observation is dependent on adaptation of the sensory system to water before tasting. Work in the author's laboratory (GED) is in general agreement with the reports of sweet taste for NaCl and other salts except that the sweetness observed is only weak before saltiness dominates the overall taste quality. Many other salts are known to exhibit sweet taste including beryllium (II) and lead (II) salts. Little analysis of the sweetness potencies of these salts appears to have been done, no doubt because of their significant toxicities. Rare earth salts, specifically $LaCl_3$, $TbCl_3$, and $EuCl_3$, have been observed to be potently sweet in the author's laboratory. All exhibit similar sweetness potencies [$P_w(5) = c.\ 100$] but are disadvantaged in that they

are strongly astringent as well as bitter in taste (DuBois, G. E., 2003).

4.02.2.3 Sensory Properties of Sweeteners

As is clear from the discussion above in II. A-D, many, many chemical compounds exhibit sweet taste. However, because of their natural occurrence in common fruits and vegetables, CHO sweeteners, and sucrose in particular, have become the consumer's standards for sweet taste. And it has been found that the synthetic and natural noncaloric sweeteners exhibit sweet tastes that differ from the tastes of CHO sweeteners in several ways. Principal differences include the following:

4.02.2.3.1 Concentration/response functions

Over the years, it has become common practice to define the sweetness potencies of sweeteners relative to sucrose as a reference. In doing so, the author (GED) *et al.* (1990) of The NutraSweet Company reported the finding that CHO sweetener potencies are independent of sucrose reference concentration while, in contrast, all synthetic and natural noncaloric sweeteners are strongly dependent on sucrose reference concentration. And it was demonstrated that the concentration/response (C/R) functions, where R is in units of percent sucrose equivalents, for all synthetic and natural noncaloric sweeteners are well modeled by the law of mass action $R = R_m C/(k_d + C)$, where R_m is the maximal response and k_d is the apparent sweetener/receptor dissociation constant. From these findings, the conclusion was drawn that all CHO sweeteners have a common R_m while all synthetic and natural noncaloric sweeteners have lower R_ms. Although other interpretations are possible, the data are consistent with the idea that all noncaloric sweeteners are partial agonists relative to CHO sweeteners. Exemplary of C/R function behavior of noncaloric sweeteners are the C/R functions for sodium saccharin and sodium cyclamate which are illustrated in Figure 13.

4.02.2.3.2 Flavor profiles

In general, CHO sweeteners exhibit clean sweet tastes without bitter, sour, salty, or savory taste attributes. This is not generally the case, however, for synthetic and natural noncaloric sweeteners. In fact, clean sweet taste is the exception rather than the rule for noncaloric sweeteners. Bitter off taste is a common off taste among noncaloric sweeteners and is particularly noticeable in saccharin. It has now been demonstrated that the bitter off taste of saccharin is due to activation of specific bitterant receptors (Pronin, A. N. *et al.*, 2004). Exemplary of flavor profiles for noncaloric sweeteners are the flavor profiles for sodium saccharin and sodium cyclamate which are illustrated in Figure 14.

4.02.2.3.3 Temporal profiles

CHO sweeteners exhibit rapid onset of sweet taste and sweetness which dissipates relatively quickly. In general, all synthetic and natural noncaloric sweeteners exhibit sweet tastes which develop more slowly and which then dissipate more slowly, oftentimes very slowly. In a very recent report, Michael Naim and co-workers of Hebrew University speculate that the lingering sweetness character of many noncaloric sweeteners may be due to inhibition of a specific G-protein receptor kinase which is responsible for termination of receptor signaling (Zubare-Samuelov, M. *et al.*, 2005). Although this is a possible explanation, the cause of the atypical temporal profiles of noncaloric sweeteners remains to be determined with certainty.

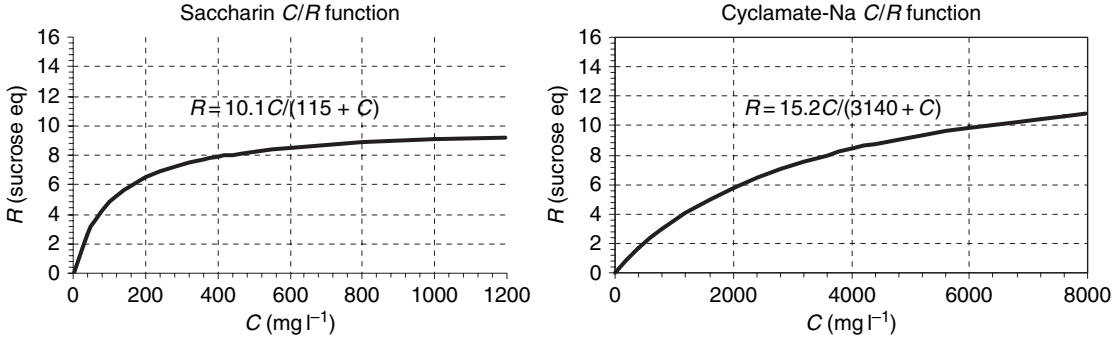

Figure 13 Concentration/response functions for sodium saccharin and sodium cyclamate.

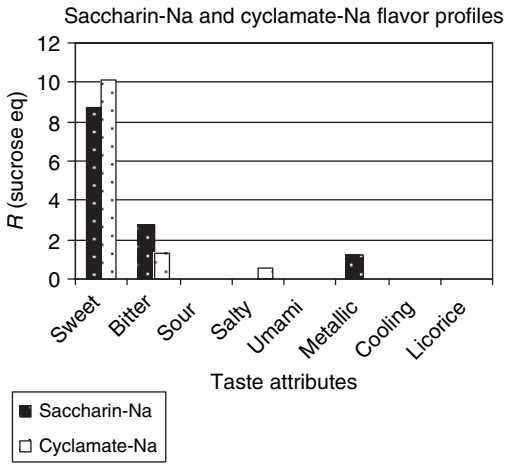

Figure 14 Comparison of flavor profiles of sodium saccharin and sodium cyclamate.

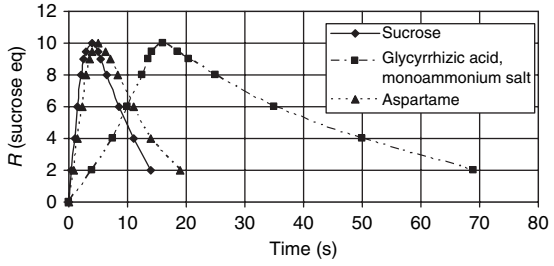

Figure 15 Comparison of temporal profiles of sucrose, aspartame, and monoammonium glycyrrhizinate.

Exemplary of temporal profiles for noncaloric sweeteners are the temporal profiles for sucrose, aspartame, and monoammonium glycyrrhizinate which are illustrated in Figure 15.

4.02.2.3.4 Adaptation

If a CHO sweetener is tasted iteratively over a short period of time, little change in sweetness intensity is noted. However, synthetic and natural noncaloric sweeteners exhibit significant decrements in perceived sweetness. The sensory system appears to desensitize to the noncaloric sweeteners to a much greater extent than is the case for CHO sweeteners. It is generally true that signaling from GPCRs is terminated by receptor phosphorylation by specific intracellular kinases. However, even if this is the case with the sweetener receptor, it is not clear as to why the desensitization following receptor activation with noncaloric sweeteners should exceed that promoted by CHO sweeteners. Exemplary of the desensitization differences between CHO sweeteners and noncaloric sweeteners are the sensory panel estimates of sweetness intensity on iterative tasting of cola beverages sweetened with HFSS, aspartame, and an aryl urea type sweetener as is illustrated in Figure 16.

4.02.3 Bitter-Tasting Stimuli

It is generally accepted that the sense of bitter taste evolved as a mechanism whereby potentially toxic substances could be avoided. In fact, a great many natural and synthetic chemical compounds which exhibit toxicity are bitter in taste at some concentration. It is not apparent, however, that thresholds for bitter taste correlate well with thresholds for toxicity. And many perfectly safe naturally occurring compounds exhibit bitterness (e.g., caffeine and quinine) and provide desirable sensory attributes to foods and beverages. Still other bitter compounds (e.g., vitamins, minerals, and bioflavonoids) provide nutritional benefits. Another confounding factor is that some very toxic compounds (e.g., lead salts and beryllium salts) are not bitter and, to the contrary, are sweet. As a bottom line, bitter taste sensation, at best, may only be considered as a first line of defense against ingestion of toxic chemical compounds.

4.02.3.1 Biochemistry of Bitter Taste

A great deal of work has been done to elucidate the biochemical pathways that mediate the sense of bitter taste. And while a historical summary of this work is beyond the scope of this review, a few key discoveries will be pointed out preliminarily to a concise discussion of the current understanding of the biochemistry of bitter taste. Many reviews of the older literature are available and included among them are Belitz H. D. *et al.* (1985), Shallenberger R. S. (1993), Beauchamp G. K. (1994), and Roy G. (1997). In our view, the SAR for bitter-tasting compounds can only be appreciated after the mechanistic pathways that mediate bitter taste are understood.

Chemists have long been fascinated with the very high level of structural diversity among bitter-tasting chemical compounds. And, at least in part, because of this extraordinary diversity, Spielman A. I. *et al.*, (1992) had already concluded by the early 1990s that multiple mechanistic pathways must be involved. Also in the early 1990s, support was provided that bitter taste, at least for

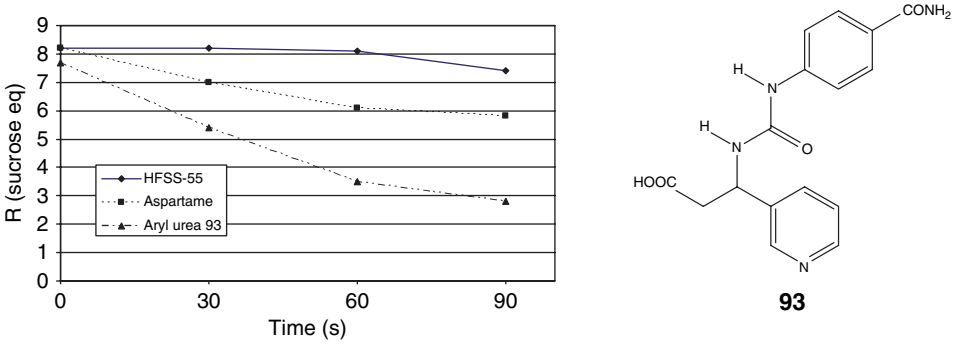

Figure 16 Comparison of the rates of sensory desensitization to HFSS-55, aspartame, and *N*-(4-carboxamidophenyl)-*N*′-(1-(3-pyridyl)-2-carboxy)-ethyl-urea (**93**) in a cola beverage system.

many compounds, must be mediated by one or more GPCRs. The support for GPCR involvement was the discovery of the G-protein gustducin and the demonstration that mice lacking gustducin could not detect common bitterants (Margolskee, R. L., 2004). The major breakthrough in understanding the biochemistry of bitter taste did not occur, however, until 2000. At this time, mouse and human genomic analysis led to the discovery of families of GPCRs referred to as T2Rs and these receptors were shown to be mediators of bitter taste signaling (Adler, E. *et al.*, 2000; Chandrashekar, J. *et al.*, 2000; Matsunami, H. *et al.*, 2000). More recently, comprehensive analysis of the human genome led to the conclusion that human bitter taste is mediated by a family of 25 T2Rs which are all expressed in the same subset of TBCs (Pronin, A. N. *et al.*, 2004). And, at the present time, substantial efforts are in place to identify the ligands which activate these 25 T2Rs, a process commonly referred to as deorphanization. Results to date include the finding (Bufe, B. *et al.*, 2002) that T2R16 mediates the activities of bitter glucopyranosides such as salicin and that T2R10 mediates the activity of strychnine. Additional findings (Pronin, A. N. *et al.*, 2004) include that T2R44 is activated by denatonium chloride and 6-nitrosaccharin and that T2R61 is activated by 6-nitrosaccharin. Extensive work is underway at this time to deorphanize all of the bitterant receptors. The finding that T2R44 responds to bitterants as diverse in structure as 6-nitrosaccharin and denatonium chloride, however, merits comment. It seems highly likely that bitter compounds will activate multiple receptors and the exception will be that a particular bitterant will activate a single T2R. And, in this sense, the bitter taste system may be similar to the olfactory system where individual odorants typically activate multiple members of the set of 350–400 human olfactory receptors. The T2Rs and olfactory receptors are similar in structure, all being family A GPCRs, and are thought to bind their ligands at conserved agonist binding sites within the TMD. It should also be noted that while the primary structures of the T2Rs are known, the structures of the functional bitterant receptors are not. The principal complication is that many GPCRs exist in dimeric and perhaps even oligomeric forms (Breitwieser, G. E., 2004). If the bitterant receptors are dimeric, are they limited to homodimers or are they heterodimeric as well? If they are only homodimeric, then 25 T2Rs will enable formation of 25 $(T2R)_2$ receptors. If, however, all possible heterodimeric receptors form as well, the number of functional receptors will be 325. In view of the highly diverse relationship between chemical structure and bitter taste, such a large number of bitterant receptors would not be a surprise.

So, it appears that the dominant pathway for initiation of the bitter taste signaling process is activation of one or more T2Rs. The next question is how do activated T2Rs excite TBCs? As already noted, the G-protein gustducin is required for TBC responses to bitterants. And so, the question really is, how does activated gustducin lead to TBC excitation? The answer began to emerge in 2002 in work done in the Margolskee laboratory (Pérez, C. A. *et al.*, 2002). In differential cDNA screening experiments in mouse TBCs, they found the common expression of several transduction elements including the α subunit of gustducin ($G_{\alpha gust}$), the G-protein subunit $G_{\gamma 13}$, the enzyme phospholipase $C_{\beta 2}$ ($PLC_{\beta 2}$), the inositol 1,4,5-trisphosphate (IP_3) receptor type III (IP_3R3), and the TRP m5

ion channel (TRPM5). And they proposed that activated gustducin initiates a cascade of reactions as follows:

1. activation of $PLC_{\beta 2}$ to convert phosphatidylinositol to IP_3,
2. action by IP_3 at its intracellular receptor IP_3R3 to promote release of Ca^{2+} from intracellular storage vesicles, and
3. Ca^{2+} binding to an intracellular site on the ion channel TRPM5 causing the channel to open allowing cations to enter the cell, thus causing the depolarization requisite for TBC excitation.

Strong support for this proposal was provided by a collaborative team from the Charles Zuker and Nicholds Ryba laboratories (Zhang, Y. *et al.*, 2003) that developed strains of mice in which expression of $PLC_{\beta 2}$ and TRPM5, respectively, were knocked out. The strain lacking $PLC_{\beta 2}$ was demonstrated to be incapable of responding to any of bitter, sweet, or umami taste stimuli. The same finding was made with the strain lacking TRPM5. This work demonstrated that responses to sweet, bitter, and umami stimuli are transduced by a common pathway and suggested that their signaling must be initiated by separate subsets of TBCs. This was demonstrated to be the case by developing a strain of mice from a $PLC_{\beta 2}$ knockout strain in which $PLC_{\beta 2}$ function was restored only in bitterant receptor expressing cells. These mice were found to have sensitivity to bitter stimuli but not to sweet or umami stimuli. Thus, it appears that coding of taste quality occurs at the cellular level. And therefore, some TBCs are sweetener sensors, some bitterant sensors and some umami sensors. This finding is consistent with work by Hellekant G. *et al.* (1997) showing that chimpanzee single CT nerve fibers emanating from taste buds show strong taste modality specificity. In general, fibers responding to the bitterants caffeine, quinine HCl, and denatonium benzoate were unresponsive to sucrose and fructose (sweet), citric acid (sour), NaCl (salty), and monosodium glutamate (umami). So, as a bottom line, some TBCs are bitterant-specific and they communicate with the brain via labeled lines so as to preserve their sensory quality coding.

Given that bitter taste may result from activation of any of 25, or even as many as 325, bitterant receptors in the bitter-sensitive subset of TBCs, it is obvious that a very broad bitterant SAR is to be expected. A finding that leads to the expectation of an even more diverse bitterant SAR is the observation that at least some bitter-tasting compounds readily cross the membranes of TBCs on a time scale consistent with the taste experience (Naim, M. *et al.*, 2002). Specifically the bitterants quinine and c-(Leu-Trp) were shown to readily accumulate at significant levels in TBCs within 1–2 s. As a result of these findings, Naim and coworkers speculated that many bitterants may initiate their effects at intracellular sites in the bitter-sensitive TBC activation cascade. In support of this idea, further work with TRPM5 (Damak, S. *et al.*, 2006) and $PLC_{\beta 2}$ (Dotson *et al.*, 2005) knockout mice indicates that other sites could be involved in bitter signaling as these mice show some aversive responses at high concentrations of bitter compounds. In summary, for bitter taste, we have 25 bitterant receptors and at least 4 major intracellular components (i.e., gustducin, $PLC_{\beta 2}$, IP_3R3, and TRPM5) that, in principle, may be sites of action for bitter-tasting chemical compounds. Without any knowledge of the SAR of bitterant compounds, the biochemistry of bitterant taste leads to the expectation of an extraordinarily diverse SAR.

As has already been noted, the bitterant SAR is an extraordinary diverse relationship as may be understood now based on the biochemistry of bitter taste. Volumes could be filled with the chemical structures of compounds reported to exhibit bitter taste. As a bottom line, it appears that bitter taste is the default taste. Thus as a general rule, if a compound's taste is not sweet, umami, sour, or salty, it will be bitter. The only factor in question is bitterness potency. Clearly, since bitterness is mediated by a family of membrane receptors, and probably by intracellular effectors as well, some bitterants will have high receptor affinities and some will not, thus resulting in a range of potencies. While this general rule is consistent with empirical observations on taste, poorly soluble compounds may appear to be exceptions. Clearly, in order to activate receptors, compounds must be in solution at sufficiently high concentration to reach their taste detection thresholds. And some apparently tasteless compounds are probably tasteless only because they are insufficiently soluble to initiate a threshold level of receptor activation. In such series of compounds, analogs of the poorly soluble compounds with higher solubility always exhibit taste and, almost always, it is bitter taste.

Interestingly, for some compounds thought to be purely sweet in taste, desensitization to sweet taste leads to bitterness perception (DuBois, G., 1985). It seems possible that signaling by sweet-sensitive

TBCs may be able to inhibit bitter-sensitive TBC signaling, an inhibition effect that is eliminated following desensitization of sweet-sensitive TBCs. Thus, for example, iterative tasting of a high concentration of aspartame results in aspartame exhibiting pronounced bitterness. Other highly hydrophilic sweeteners (e.g., sucrose, fructose, glucose) exhibit no bitterness at all even after attempted desensitization. Thus, it appears that some threshold hydrophobicity must be necessary for organic compounds to stimulate bitter-sensitive TBCs. Organic compounds that are too hydrophilic appear incapable of activating bitter-sensitive TBCs. Yet many inorganic compounds which are extremely hydrophilic are capable of activating bitter-sensitive TBCs. Many organic compounds are known which exhibit both sweet and bitter tastes. Typically such compounds exhibit only sweetness when evaluated at concentrations just above their taste thresholds, but at higher concentrations exhibit both sweet and bitter tastes. In such cases, it appears that sweet-sensitive TBCs are not able to inhibit activities of bitter-sensitive TBCs. It could be that the inhibitory effect of sweet-sensitive TBCs on bitter-sensitive cells only occurs when there is a wide difference between sweetness and bitterness potencies for compounds.

4.02.3.2 Bitterant Structure–Activity Relationship

An objective of this review is to summarize the SAR of bitter stimuli. However, given the extraordinary diversity of bitterant SAR, it would be of little value to provide a comprehensive listing of chemical compounds which have been reported to exhibit bitter taste. So, rather than attempt such a feat, a listing is provided of common bitter compounds that are either used in research or are present in common foods. Chemical structures, empirical formulas, and molecular weights are provided. Bitterant potencies are not generally available as is the case for sweetener potencies. Bitter taste has generally been a taste that food, beverage, and pharmaceutical manufacturers have tried to eliminate or minimize. And for this reason, there has not been a great deal of research in which bitterant potencies have been systematically determined as has been the case in the sweetener field. In some cases, bitter taste recognition thresholds (BRTs) have been reported as has been summarized by Glendinning J. I. (1994a; 1994b) and Belitz H.-D. and Wieser H. (1985).

A listing of ten common naturally occurring bitterants **94–103**, selected to illustrate the extraordinary diversity of bitterant SAR, with structures, molecular weights, empirical formulas, and BRT information provided in Figure 17, is as follows:

1. *Urea (94)*. Ureas in general are bitter in taste with the simplest member of the series exhibiting bitterness and bitterness potency increasing 100-fold on substitution with hydrophobic groups.
2. *Potassium chloride (95)*. KCl is commonly employed as a salt substitute by people suffering from hypertension. Its use is limited, however, by the presence of pronounced bitterness in addition to saltiness. Many other inorganic salts also exhibit bitter taste.
3. *Nicotine (96)*. Alkaloids, in general, are bitter in taste with nicotine being one of the simplest members of this class of compounds. It is the physiologically active and addictive component present in tobacco smoke.
4. *Caffeine (97)*. Caffeine is a fully methylated purine base present in many natural products including coffee beans, tea leaves and cola nuts. It, like other purine and pyrimidine bases, exhibits bitter taste.
5. *Catechin (98)*. Catechin is a flavanoid commonly found in tea.
6. *Quinine (99)*. Quinine is the most abundant alkaloid in the bark of the cinchona tree which is indigenous to South America. It was originally commercialized as an antimalarial but today is commonly employed as a bitterant in foods and beverages.
7. *Humulone (100)*. Humulone and related compounds are the bitter principles in hops which are key ingredients in beer.
8. *Limonin (101)*. Limonin is a member of the triterpenoid class of natural products and is the primary bitter principle in lemon and some other citrus fruit. It is a member of a group of natural products referred to as limonoids, all of which are bitter in taste.
9. *Naringin (102)*. Naringin is a member of a class of natural products known as flavanoid glycosides and is the principal bitter component present in the peel of grapefruit.
10. *Digitoxin (103)*. Digitoxin is a steroidal cardiac glycoside present in the plant *Digitalis purpurea* and is representative of a great many triterpenoid glycoside natural products, nearly all of which exhibit potent bitter taste.

A listing of ten bitterants, **104–113**, principally of synthetic origin, selected to further illustrate the

extraordinary diversity of bitterant SAR, with structures, molecular weights, empirical formulas, and BRT information provided in Figure 18, is as follows:

1. *Cyclohexylamine (**104**).* Aliphatic amines in general are bitter-tasting compounds with bitterness potency increasing with the size of the aliphatic substituent. Interestingly, on sulfamation (i.e., R-NH_2 → R-$NHSO_3^-$ Na^+) the bitter-tasting cyclohexylamine is converted into a sweet-tasting sulfamate salt commonly known as sodium cyclamate.
2. *Ethylpyrazine (**105**).* Pyrazines are important flavor compounds exhibiting nutty and coffee-like aromatic characters. As a class of compounds,

Figure 18 Chemical structures, molecular weights, empirical formulas, and bitterness recognition thresholds of some synthetic bitter-tasting chemical compounds. [a]Belitz H.-D. and Wieser H. (1985); [b]Chang W. I. *et al.* (2006); [c]Saroli A. (1986); and [d]Boughter J. D. and Whitney G. (1993).

however, they are generally bitter in taste with bitterness potency increasing with hydrophobicity.

3. *6-n-Propylthiouracil (PROP) (106).* Thioureas are quite generally bitter in taste. PROP is a compound of substantial interest in that people exhibit a bimodal distribution in sensitivity to its bitterness with some individuals highly sensitive to its bitterness and some only sensitive to it at much higher concentrations. This difference in sensitivity has been demonstrated to have a genetic origin and is believed to be due to a mutation in T2R4 (Chandrashekar, J. *et al.*, 2000).

4. *18-Crown-6 (**107**).* Crown ethers are uniformly bitter in taste with bitterness potency increasing with hydrophobicity.
5. *Adenosine (**108**).* Purine and pyrimidine nucleosides as well as their bases are generally bitter, where the deoxyribosides are more potently bitter than the ribosides and nucleotides are generally not bitter. As in other series of compounds, bitterness potency increases with hydrophobicity.
6. *cis-9,12,13-Tri-hydroxyoct-10-enoic acid (**109**).* Hydroxylated fatty acids are common products of lipolysis and lipoxidation and are uniformly bitter. Such fat degradation products are responsible for the bitter off taste of many cereal and soy-based products.
7. *Denatonium salts (**110**).* Quaternary ammonium salts in general are bitter in taste, although the most potent bitterants reported are denatonium salts as reported by Saroli A. (1986). Denatonium salts are commonly employed bitter stimulants employed in mechanistic studies in animal models.
8. *2,6,1′,6′-Tetrachloro-2,6,1′,6′-tetradeoxy-mannosucrose (**111**).* Many halogenated deoxy sucrose derivatives are potently sweet compounds. Of particular note are 4,1′,6′-trichlorotrideoxygalactosucrose (sucralose) and 4,6,1′,6′-tetrachloro-galactosucrose which are potent sweeteners. Interestingly, a few halogenated deoxy sucrose derivatives are potently bitter, with some such as **111** matching quinine in bitterness potency.
9. *(L)-Phenylalanyl-glycyl-(L)-phenylalanyl-glycine (**112**).* Peptides, quite generally, are bitter as are hydrophobic amino acids. The exceptions are a few amino acids (e.g., glycine, D- and L-alanine, D-phenylalanine, and D-tryptophan) and a few peptide derivatives (e.g., aspartame) which are sweet in taste. And, as is the general trend, bitterness potency in such series of compounds increases with hydrophobicity. Many foods acquire bitter tastes due to the formation of bitter peptides on enzymatic breakdown of proteins. Tetrapeptide **112** is just one of the many bitter peptides which have been reported.
10. *Sucrose octaacetate (**113**).* Acetylated sugars in general exhibit bitter taste, and sucrose octaacetate has been used extensively in the study of bitter taste in humans and animal model systems.

4.02.4 Umami-Tasting Stimuli

Until the close of the twentieth century, for many, taste was considered to be one of the five senses which may be subdivided into four basic tastes: sweet, sour, salty, and bitter. Even though this is the case, evidence began to accumulate for a fifth basic taste, savory taste. The first claim for savory taste was by Ikeda K. (1909) who isolated glutamic acid from a seaweed source and argued that its taste was unique. As the monosodium salt, the taste is savory and was given the Japanese word *umami* which means delicious. The literature on umami taste has been reviewed quite comprehensively by Kawamura Y. and Kare M. R. (1987) and more recently by Bellisle F. (1999).

4.02.4.1 Biochemistry of Umami Taste

At the beginning of the twenty-first century, conclusive evidence that umami taste is a fifth basic taste began to accumulate. First, Nirupa Chaudhari and associates (2000) at the University of Miami obtained evidence suggesting that the umami taste receptor is a truncated form of the metabotrophic glutamate receptor mGluR4. Shortly thereafter, a collaborative team from the laboratories of Charles Zuker and Nicholas Ryba reported discovery of a mouse amino acid receptor (Nelson, G. *et al.*, 2002). In a functional assay in HEK-293 cells, they showed that glutamic acid activity, as well as the activities of many other L-amino acids, is mediated by a single receptor, apparently a heterodimer of two 7-TMD proteins which they named T1R1 and T1R3, often written as T1R1/T1R3. Both T1R1 and T1R3 are members of the small family of class C GPCRs and T1R3 is the same 7-TMD protein present in the sweetener receptor T1R2/T1R3 already discussed. The rat amino acid receptor discovery was quickly followed by a report by Li X. *et al.* (2002) of Senomyx (La Jolla, CA) on parallel findings for the human system. HEK-293 cells, in which both human T1R1 and T1R3 were expressed, responded to L-glutamic acid in a manner consistent with expectation from sensory experiments. L-Aspartic acid was also active but all other amino acids tested were essentially inactive. Thus, while the rodent receptor is a general L-amino acid receptor, the human receptor is specific for glutamate and aspartate. In addition, inosine monophosphate (IMP) and other nucleotides, which appear synergistic with monosodium glutamate in

taste tests, exhibited strong enhancements *in vitro*. On further analysis, it was learned that, in the absence of glutamate, these nucleotides are inactive. And therefore, they are not synergistic with glutamate. They are really enhancers of glutamate taste activity and likely function at the receptor as positive allosteric modulators. Positive and negative allosteric modulators of agonist activity are now known for many family C GPCRs as has been reviewed (Goudet, C. *et al.*, 2004).

Family C GPCRs are generally thought to bind their agonists within their large extracellular VFDs. Since the umami receptor is a heterodimeric receptor and since the umami and sweetener receptors contain the common subunit T1R3, it is thought, though not yet proven, that the glutamate binding site is most likely in the VFD of T1R1. Many other umami taste agonists have been identified as are reviewed below. Do they all bind in the glutamate binding site? In view of the finding that the closely related sweetener receptor T1R2/T1R3 binds agonists at no less than three sites, it seems likely that umami taste agonists also initiate their activities at a plurality of binding sites on T1R1/T1R3.

Sweet, bitter, and umami tastes are transduced by a common biochemical pathway. Experiments with gustducin and transducin knockout mice demonstrate that both of these G proteins mediate umami taste (He, W. *et al.*, 2004). Other work with $PLC_{\beta 2}$ and TRPM5 knockout mice demonstrates the critical role for both of these effectors in umami taste (Zhang, Y. *et al.*, 2003). In summary, while the role of the truncated mGluR4 receptor is not yet clear, there is a general consensus that umami taste is primarily mediated by a receptor T1R1/T1R3 as well as several intracellular effectors (i.e., gustducin, $PLC_{\beta 2}$, IP_3R, and TRPM5). It is also known that umami taste quality is coded at the cellular level, just as is the case for sweet and bitter taste qualities. Thus, within the taste bud, some TBCs are specific sensors for umami taste stimuli. They differ from the sweet- and bitter-sensitive TBCs in that they uniquely express the umami taste receptor T1R1/T1R3, while not expressing the sweetener receptor T1R2/T1R3 or bitterant T2R receptors.

4.02.4.2 Umami Tastant Structure–Activity Relationship

An objective of this review is to summarize the SAR of umami taste stimuli. Efforts aimed at discovery of novel umami tastants have not received the same intensity of focus as efforts to find novel sweeteners or to determine the structures of natural sweeteners or bitterants. Nonetheless, some umami tastant discovery work has been carried out in recent years and eight umami tastants **114**–**121**, with structures, molecular weights, empirical formulas, and umami taste potency information provided, are illustrated in Figure 19. Some di-, tri-, and tetra-peptides including Glu-Asp, Glu-Glu, Asp-Glu, Thr-Glu, Asp-Glu-Ser, Glu-Gly-Ser, Asp-Asp-Asp-Asp, and even the octapeptide Lys-Gly-Asp-Glu-Glu-Ser-Leu-Ala have been reported in the literature to exhibit umami taste. However, recent studies, as reviewed by Beksan E. *et al.* (2003), do not support the presence of umami taste in any of these compounds.

The purine nucleotides IMP (**122**), guanosine monophosphate (GMP (**123**)), and adenosine monophosphate (AMP (**124**)), as well as many synthetic analogs, have been reported to exhibit umami taste, as has been reviewed by Yamaguchi S. (1979). The chemical structures, empirical formulas, molecular weights, and relative umami taste activities are provided in Figure 20. In addition to exhibiting umami tastes themselves, these compounds are claimed to be strongly synergistic with monosodium glutamate. However, in the *in vitro* studies on the rat umami receptor carried out by Nelson G. *et al.* (2002) and on the human umami receptor carried out by Li X. *et al.* (2002), it was demonstrated that these purine nucleotides are inactive at the umami receptor if evaluated in the absence of glutamate or other amino acids with umami taste. Normally, in the *in vitro* receptor assays carried out in heterologous cell systems, the extracellular fluid contains low levels of amino acids. And, under these conditions, purine nucleotides were observed to exhibit activity. However, to ensure that the activity observed was due to the purine nucleotides rather than an enhancement effect of endogenous amino acids, the cell preparations were washed with amino acid free saline immediately before assay. Under these conditions, purine nucleotides give no responses while glutamate still exhibits its typical activity. Control cell preparations lacking the umami taste receptor are also unresponsive to purine nucleotides even without the cell washing step, thus providing evidence that the enhancement effect of purine nucleotides is receptor-mediated. In summary, it appears that purine nucleotides are not umami receptor agonists but are enhancers, presumably positive allosteric modulators, of glutamate and other amino acids. An observation consistent with

this conclusion is that, while 0.1 mM IMP exhibits a weak umami taste, no increase in umami taste intensity is observed for 1.0 and 10.0 mM solutions (DuBois, G. E. and San Miguel, R. S., 2005). It appears that 0.1 mM IMP is sufficient to maximally enhance the umami taste of the glutamate endogenous to saliva and thus increased IMP levels are without effect. Since purine nucleotides are not umami taste agonists, the umami taste activities provided for the examples in Figure 20 are really metrics for their relative potencies as enhancers of the umami taste of umami agonists (i.e., glutamate and aspartate) in human saliva. It is noteworthy that IMP, GMP, and AMP exhibit quite significant differences in activity as would be expected for a receptor-mediated effect.

4.02.5 Sour-Tasting Stimuli

Sour taste has always been accepted as one of the primary tastes and is very important to the enjoyment of many foods and beverages, especially those with sweet tastes. Here we provide a review of the current understanding of the cellular pathways which

mediate sour taste followed by a review of knowledge on the taste of acids that are commonly used in foods and beverages.

4.02.5.1 Biochemistry of Sour Taste

There is no question that sour taste is a unique and primary taste, but yet, in spite of its importance to our daily enjoyment of foods and beverages, until quite recently, the biochemical pathways which mediate it were largely unknown. Then, evidence began to accumulate that it must be an ion channel-mediated activation pathway in specific subsets of TBCs. Sour taste is the response to acids. All acidic chemical compounds are sour in taste. Here we discuss pH homeostasis in the body and the role that sour taste sensation plays in it, the biochemical mechanisms for excitation of acid-sensitive TBCs, and the rationale for difference in sour taste for different acids.

pH homeostasis and sour taste. A unique characteristic of living organisms is that they maintain their internal milieu at constant pH. Even small deviations from the physiological pH can be life threatening for most organisms. Therefore, organisms have developed efficient cellular mechanisms to detect the presence of H^+ or acid equivalents in their immediate environment and to limit acid entry into their internal milieu. However, if some acid is absorbed into the internal milieu, it is immediately buffered and ultimately excreted. For the detection of acid in their environment most animal species rely on sour taste, and to a lesser extent on the sense of smell. Sour taste is elicited by acidic stimuli and is detected by a subset of specialized TBCs in the oral cavity referred to as acid-sensing TBCs. Many of the foods, juices, and beverages that humans consume are acidic in nature (Feldman, M. and Barnett, C.,1995). In humans, sour taste evokes an innate rejection response to extremely acidic or sour stimuli, limiting the *ad libitum* ingestion of acid (Beauchamp, G. K. *et al.*, 1991; Scott, T. R. and Plata-Salaman, C. R., 1991). In this regard, along with the lungs and kidneys, which are the primary organs for acid secretion, acid-sensing TBCs in the oral cavity, by restricting the intake of acid, function as part of a multiorgan system to maintain acid–base homeostasis.

Acid-sensing. Since most acids decrease extracellular pH (pH_o), it would seem reasonable to think that a decrease in the pH_o in the oral cavity should be the signal for sour taste transduction. However, if that were the case, one would expect all acids at the same pH_o to taste equally sour. In our everyday experience and in animal model systems, different acids at same pH_o do not elicit the same neural responses or give the same perception of sourness (Beidler, L. M., 1967; Beidler, L. M. and Gross, G. W., 1971; Ogiso, K. *et al.*, 2000). In animal models it is well recognized that acetic acid at a fixed pH is always a more potent sour stimulus than an equivalent pH strong acid, such as HCl (Lyall, V. *et al.*, 2001). This indicates that a decrease in pH_o is not the signal for sour taste transduction. However, changes in intracellular pH (pH_i) of TBCs have been shown to correlate extremely well with the neural responses, indicating that it is the decrease in pH_i that is the proximate signal for sour taste transduction (Lyall, V. *et al.*, 2001; 2002a; 2002b; 2004; 2006).

Mechanisms for acid entry to TBCs. Acid transduction begins with the entry of H^+ or acid equivalents across the apical membrane of TBCs that causes a decrease in intracellular pH (pH_i) of acid-sensing TBCs. Acids exist in two forms: fully dissociated strong acids (e.g., HCl) and weak organic acids (e.g., acetic acid or citric acid) or dissolved CO_2, the precursor of carbonic acid. Accordingly, there are acid entry mechanisms for both strong and weak acids in the apical membrane of TBCs. For strong acids, acid entry involves H^+ flux through an apical proton channel that is blocked by divalent metal ions Zn^{2+} or Cd^{2+} (Lyall, V. *et al.*, unpublished observations). This channel is amiloride- and Ca^{2+}-insensitive but is activated by an increase in intracellular adenosine 3′,5′-cyclic monophosphate (cAMP) (Lyall, V. *et al.*, 2002a; 2004). However, there is some evidence to suggest that H^+-gated channels, such as the acid-sensing ion channel (ASIC) in the apical membrane and both ASIC (Ugawa S., *et al.*, 1998; Lin, W. *et al.*, 2002) and hyperpolarization-activated channels (HCN) (Stevens, D. R. *et al.*, 2001) in the basolateral membrane of TRCs, and TASK-2, a two pore domain K^+ channel (Lin, W. *et al.*, 2004; Richter, T. A. *et al.*, 2004a), may also play a role in sour taste transduction. These channels in the basolateral membrane could be activated if H^+ can cross tight junctions and decrease pH in the basolateral compartment. In mice, ASIC2 is not required for acid taste (Richter, T. A. *et al.*, 2004b) suggesting that at least in mice, ASIC channels do not play a major role in acid-sensing.

In contrast, weak organic acids do not seem to have apical membrane receptors. They enter TBCs across the apical membrane by passive diffusion as lipid-soluble undissociated neutral molecules. Once inside the

cell they dissociate to generate H^+ intracellularly and decrease TBC pH_i (Lyall, V. *et al.*, 2001). For example, in the case of dissolved CO_2, the CO_2 molecules passively enter TBCs across the apical membrane and combine with H_2O in a reaction catalyzed by intracellular carbonic anhydrases to form carbonic acid (H_2CO_3), which then dissociates to yield $H^+ + HCO_3^-$.

Taste receptor cells also contain NPPB (**125**) sensitive stretch-activated Cl^- channels (Gilbertson, T. A., 2002). The presence of an NPPB-sensitive Cl^- channel activated by acid was demonstrated in mouse taste cells (Miyamoto, T., *et al.*, 1998), suggesting a role for Cl^- channels in acid taste transduction. In addition to Cl^- channels, there is also evidence that an NPPB-insensitive poorly selective cationic conductance in the apical receptive membranes of mouse TBCs may also be involved in sour taste transduction (Miyamoto, T., *et al.*, 1998). In summary, sour taste transduction is mediated via multiple pathways. Similarly, in the case of other acid-sensitive cells, such as the central chemosensitive neurons, a multiple factors model has been proposed for acid signaling (Putnam, R. W. *et al.*, 2004).

Neural responses to acidic stimuli. A decrease in TBC pH_i is responsible for the neural response profiles to acidic stimuli. Acidic stimuli elicit both CT and glossopharyngeal taste nerve responses that are composed of two components with distinct temporal characteristics. A rapid transient increase in the phasic neural response slowly declines to a quasi-steady state, defined as the tonic phase of the neural response. Treating rat tongue with specific membrane permeable blockers of carbonic anhydrases MK-417 (**126**) or MK-507 (**127**) inhibits both the phasic and tonic components of the CT response to CO_2 (Lyall, V. *et al.*, 2001; 2002b). This indicates that an acid-induced decrease in TBC pH_i is necessary to elicit both the phasic and the tonic components of the CT response to acid stimulation.

Following a decrease in pH_i, the proximate sour stimulus, the downstream transduction mechanisms for the phasic and tonic components of the CT response to acid stimulation follow distinct and separate pathways. An acid-induced decrease in pH_i of acid-sensing TBCs alters the cell cytoskeleton by shifting the F- to G-actin equilibrium toward G-actin resulting in cell shrinkage and by titrating the mean charge of the intracellular membrane-impermeant anions (which could include elements of the cytoskeleton) (Fraser, J. A. *et al.*, 2005). The pH_i-induced decrease in cell volume activates a flufenamic acid (**128**) sensitive shrinkage-activated nonselective cation channel (SANSCC) in the basolateral membrane of TRCs. The entry of one or more monovalent cations through SANSCC depolarizes the receptor potential and is the basis for the phasic component of the CT response to acidic stimuli. Loading TBCs *in vivo* with the Ca^{2+}-chelator, BAPTA (**129**), did not affect the phasic part of the CT response to acids (Figure 21), indicating that phasic response is indifferent to changes in cytosolic Ca^{2+} (Lyall, V. *et al.*, 2006).

In acid-sensing TBCs a decrease in pH_i is followed by an increase in intracellular Ca^{2+} ($[Ca^{2+}]_i$) (Liu, L. and Simon, S. A., 2001a; 2001b; Richter, T. A. *et al.*, 2003). An increase in TBC $[Ca^{2+}]_i$ activates basolateral Na^+-H^+-exchanger-1 (NHE-1) and results in cell volume recovery and the neural adaptation to both strong and weak acid stimuli (Lyall, V. *et al.*, 2002a; 2004; Vinnikova, A. K. *et al.*, 2004; Lyall, V. *et al.*, 2006). Neural adaptation is related to the tonic part of the CT response to acidic stimuli (Figure 22). Therefore, a primary decrease in TBC pH_i, followed by a secondary increase in $[Ca^{2+}]_i$, and the subsequent activation of basolateral NHE-1 are specific events related to the tonic part of the neural response only (Figure 23).

One unexpected outcome from work on the identity of the molecular taste receptors for sweet, bitter, and umami taste is that the molecular receptors for each of these modalities are segregated in separate subsets of receptor cells (Zhang, Y. *et al.*, 2003). Recent work on sour taste shows that this modality is also expressed uniquely in a separate

subset of taste receptor cells in the fungiform, circumvallate, and foliate papillae, and taste buds of the palate (Huang, A. L. *et al.*, 2006; Ishimaru, Y. *et al.*, 2006; Lopez-Jimenez, N. D. *et al.*, 2006). In the taste buds of the circumvallate and foliate papillae, this subset of cells expresses two unique TRP proteins, designated PKD2L1 and PKD1L3, in each cell of the subset. In fungiform and palatal taste buds,

only PKD2L1 is expressed in each of the cells of the subset. PKD2L1 and PKD1L3 localize preferentially in the apical regions of the taste receptor cells. When PKD2L1 and PKD1L3 are coexpressed in HEK cells they respond to the presence of citric acid and HCl by causing an increase in intracellular calcium concentration (Ishimaru, Y. *et al.*, 2006). It is unclear, however, if these proteins behave as calcium-conducting channels *in vivo*. That PKD2L1 containing cells are involved in sour taste is elegantly demonstrated in genetic ablation studies in which mice are engineered such that cells that would normally express PKD2L1 are destroyed by attenuated diphtheria toxin (Huang, A. L. *et al.*, 2006). In such mice, CT responses to acids were completely absent while responses to the other taste modalities remained intact. The fact that taste receptor cells lacking PKD2L1 fail to respond to weak and strong acids alike suggests that these proteins may be part of the intracellular pH-sensing system in sour taste receptor cells and in some central nervous system neurons where PKD2L1 is also expressed.

Neurotransmitter: TBCs detect the presence of acid in the oral cavity and elicit taste nerve responses. This implies that acid-induced changes in TBC pH_i, Ca^{2+}, cell shrinkage, and/or depolarization are communicated to the taste nerve fibers innervating TBCs via one or more neurotransmitters. Recent studies suggest the possible role for serotonin (**131**) (Kaya, N. *et al.*, 2004; Huang, Y. J. *et al.*, 2005) and ATP (**132**) (Finger, T. E., *et al.*, 2005). Serotonin, also known as 5-hydroxytryptamine (5-HT), is suggested to act on the 5-HT_3 receptor on the taste nerve fibers. However, the 5-HT_{3A} knockout mice did not show any differences in their neural response to taste stimuli, including acids (Finger, T. E., *et al.*, 2005), indicating that serotonin may not be the taste neurotransmitter. In contrast to 5-HT_{3A} knockout mice, in a double knockout mouse model lacking ionotropic purinergic P2X receptor units $P2X_2$ and $P2X_3$, no neural taste responses in CT or glossopharyngeal nerve were observed for salty, bitter, sweet, umami, and acidic stimuli. This suggests that ATP may be the taste-specific neurotransmitter that transmits information from TBCs to taste nerves (Figure 24).

4.02.5.2 Acidulant Structure–Activity Relationship

As already noted, all acids exhibit sour taste. The proximate event for signaling by acid-sensing TBCs is a drop in intracellular pH. Strong mineral acids (e.g., HCl, H_2SO_4, H_3PO_4) reduce intracellular pH by the diffusion of hydronium ions through an apical proton channel. Organic acids (e.g., citric acid, malic acid, tartaric acid), however, while modulating intracellular pH by the hydronium ion/apical proton channel pathway to some degree, principally reduce intracellular pH following diffusion through the TBC membrane. This mechanistic rationale suggests that mineral acids at constant pH should exhibit equal sourness while the sournesses of organic acids should not be strongly correlated with pH but should be dependent on efficiencies of diffusion into the TBC. This expectation is consistent with observations. Exemplary listings of common mineral acids and organic acids, as well as their empirical formulas, molecular weights, and pK_as, are provided in Figures 25 and 26.

4.02.6 Salty-Tasting Stimuli

Salty taste has always been accepted as one of the primary tastes and is very important to the enjoyment of many foods, especially foods with umami tastes. In fact, until the recent identification of the umami receptor, many held the belief that umami taste was a superimposition of salty and sweet tastes. In umami taste, the presence of a cation (e.g., Na^+) is critical as without it, even the prototypical umami agonist monosodium glutamate does not exhibit umami taste. Here we provide a review of the current understanding of the biochemistry of salty taste followed by a review of observations on the taste of NaCl and a few other common salts.

4.02.6.1 Biochemistry of Salty Taste

Salty taste is a unique and primary taste and in spite of its importance to our daily enjoyment of foods, until quite recently, the biochemical pathways which mediate it were largely unknown. Then, evidence began to accumulate that it must be mediated by ion channels present in specific subsets of TBCs. Salty taste is the response to NaCl, the prototypical salty taste stimulus, as well as a number of other salts. Here we discuss the biological mechanisms which mediate salt homeostasis, the ion channels which mediate the excitation of salt-sensitive TBCs and the biochemical explanation for the differences in tastes between salts of differing composition.

Sodium balance and sodium appetite. Tight regulation of the ionic composition and osmotic pressure of the extracellular fluid compartment of terrestrial mammals is fundamental to their survival. This is accomplished, in part, through the agency of the regulatory hormone, aldosterone, which increases Na^+ transport across epithelial cells from the lumina of the renal collecting duct and colon (Rossier, B. C. *et al.*, 2002). Aldosterone action, therefore, reduces Na^+ excretion in urine and feces. On the input side, changes in Na^+ balance depend on the subject's eating behavior which in turn is influenced by the sense of taste and the subject's endocrine status as determined by current Na^+ balance (Denton, D. A., 1967). For example, in Na^+-replete rats, NaCl concentrations near isotonicity tend to be preferred over water while those in the hypertonic range are increasingly less palatable (Richter, C. P., 1936; Fregly, M. J. and Rowland, N. E., 1986). Na^+-deprived and adrenalectomized rats, on the other hand, prefer even hypertonic NaCl solutions over water (Richter, C. P., 1936; Fregly, M. J. and Rowland, N. E., 1986; Scott, T. R. and Plata-Salaman, C. R., 1991). Increased salt preference has also been reported for human subjects taking diuretics on a Na^+-restricted diet (Beauchamp, G. K. *et al.*, 1990). Na^+-deficient wild rabbits taste and then readily consume Na^+ from salt licks while tasting and then rejecting nearby licks of nonsodium salts (Denten, D. A., 1967). These and other data indicate a connection between Na^+-specific taste and an animal's current interstitial fluid Na^+ levels and mineralocorticoid status.

Among the Na^+ transporters upregulated by aldosterone is the epithelial sodium channel (ENaC). ENaC is present in the membranes of various types of epithelial cells, including taste receptor cells of rats (Kretz, O. *et al.*, 1999; Lin, W. *et al.*, 1999). As such, ENaC would appear to be an excellent candidate for the Na^+-specific salt taste receptor. For the rat and other rodents, the preponderance of evidence indicates that this is the case.

Sodium taste and ENaC pharmacology. Na^+ transport across epithelia, including lingual epithelia, involves the passive flux of Na^+ from the luminal compartment (oral cavity for dorsal lingual epithelia) into the epithelial cells (for taste, receptor cells in taste buds and some surrounding nontaste epithelia) through apical membrane ENaC. Na^+ is then pumped across the basolateral membranes of the epithelial cells by the Na^+-K^+-ATPase (Verrey, F. *et al.*, 2000). Transepithelial Na^+ transport can be inhibited at the cell apical membrane by adding amiloride (**148**) or one of its analogs to the luminal solution, thereby reducing the Na^+ permeability of ENaC (Verrey, F. *et al.*, 2000). For the species in which transepithelial ion transport has been studied across the dorsal lingual epithelium, viz., dog (DeSimone, J. A. *et al.* 1984; Mierson, S. *et al.*, 1985; Simon, S. A. and Garvin, J. L., 1985), rat (Heck, G. L. *et al.*, 1984; Garvin, J. L. *et al.*, 1988; Mierson, S. *et al.*, 1988; Gilbertson, T. A. and Zhang, H., 1998), rabbit (Simon, S. A. *et al.*, 1986), and hamster (Gilbertson, T. A. and Zhang, H., 1998), the Na^+ transport paradigm appears to apply. The most compelling evidence that ENaC or some ENaC variants are indeed Na^+-specific salt taste receptor proteins is that the taste nerve response to NaCl is significantly inhibited by amiloride and its analogs in a variety of species. Taste responses to NaCl recorded in the

afferent CT or in the nucleus of the solitary tract of rat (Schiffman, S. S. *et al.*, 1983; Heck, G. L. *et al.*, 1984; Brand, J. G. *et al.*, 1985; Hill, D. L. and Bour, T. C., 1985; Yoshii, K. *et al.*, 1986; Ninomiya, Y. and Funakoshi, M., 1988; Scott, T. R. and Giza, B. K., 1990; St. John, S. J. and Smith, D. V., 2000), hamster (Hettinger, T. P. and Frank, M. E., 1990), some mouse strains (Ninomiya, Y. *et al.*, 1989), and gerbil (Schiffman, S. S. *et al.*, 1990) are significantly inhibited by amiloride without effect on responses to stimuli of other taste modalities. Amiloride sensitivity is observed in single CT units of the chimpanzee that respond strongly to Na^+ and Li^+ salts, but not in units sensitive to both Na^+ and K^+ (Hellekant, G. *et al.*, 1997). Whole cell patch clamp studies on isolated rat and hamster taste buds show that amiloride blocks a Na^+ current across taste cell membranes, consistent with a role for ENaC in Na^+ taste reception (Avenet, P. and Lindemann, B., 1988; 1991; Gilbertson, T. A. *et al.*, 1993). Taken together the data are consistent with the conclusion that ENaC is the Na^+-specific salt taste receptor in many species including many rodents and nonhuman primates. In rats the amiloride-sensitive part of the response accounts for 75–80% of the total response to 100 mM NaCl(see Figure 23). Surprisingly, ENaC appears to play less of a role in human salt taste (Smith, D. V. and Ossebaard, C. A., 1995).

In rats, ENaC appears to be functional only in the taste buds innervated by the CT, that is, principally those in fungiform papillae. Behavioral studies convincingly show that the rat's ability to discriminate between NaCl and KCl depends on taste information from the CT and this ability is progressively lost with the NaCl solutions containing increasing amiloride concentrations (Spector, A. C. *et al.*, 1996). This behavioral change correlates perfectly with the amiloride concentration dependence of the diminution of the response to NaCl in Na^+-sensitive single units of the nucleus of the solitary tract. The cumulative molecular, immunocytochemical, electrophysiological, and behavioral evidence indicates, therefore, that ENaC is a Na^+-specific salt taste receptor, and most likely the only Na^+-specific receptor.

Amiloride-insensitive salt taste reception. As seen in Figure 27, after inhibition of the NaCl response by benzamil (**149**), a significant neural response remains. Analysis of single CT units in rats (Frank, M. E. *et al.*, 1983), hamsters (Frank, M. E. *et al.*, 1988), and chimpanzees (Hellekant, G. *et al.*, 1997) suggests the existence of a salt taste receptor type that is

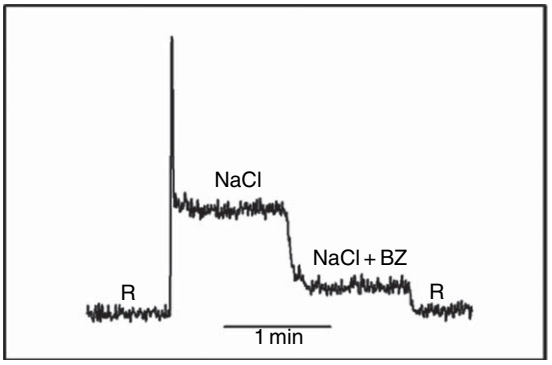

Figure 27 Integrated rat chorda tympani response to 100 mM NaCl followed by a response to 100 mM NaCl + 5 μM benzamil (**149;** Bz). R denotes the rinse solution (10 mM KCl). The NaCl response above baseline response (R) minus the NaCl + Bz response is the amiloride-sensitive part of the NaCl response (about 75% of the NaCl response).

cation-nonselective in addition to one that is Na^+-specific. Accordingly, one obvious candidate for such a taste receptor would be a nonselective cation channel. Unfortunately this fact alone does little to limit the number of possibilities, given the plethora of nonselective cation channels that have been described. One possibly fruitful approach is to seek pharmacological probes that might restrict the number of possible candidate receptor types, that is, an approach analogous to that leading to the discovery of ENaC as the Na^+-specific taste receptor through the action of its pharmacological inhibitor, amiloride. In this manner it has been shown that the amiloride-insensitive part of the NaCl CT response, as well as the responses to KCl, NH_4Cl, and $CaCl_2$, are enhanced by the vanilloids, resiniferatoxin (**150**; RTX), and capsaicin (**151**) (Lyall, V. *et al.*, x). At higher vanilloid concentrations the salt-evoked CT responses are inhibited. The amiloride-insensitive part of the NaCl CT response is completely inhibited by the vanilloid receptor-1 (VR1 or TRPV1) inhibitor, SB366971 (**152**) (Lyall, V. *et al.*, 2004). These results have led to the hypothesis that TRPV1, a nonselective cation channel, or more likely, one of its splice variants, is the nonselective cation salt taste receptor. Additional data in support of this are as follows (cf. Lyall, V. *et al.*, 2004):

1. The amiloride-insensitive part of the NaCl CT response increases with temperature and the effects of temperature and vanilloids are additive, similar to TRPV1.

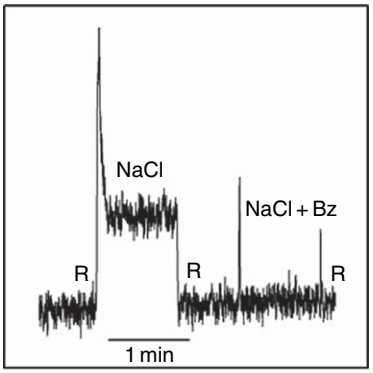

Figure 28 Integrated chorda tympani response to 100 mM NaCl and 100 mM NaCl + 5 μM benzamil (**148**; Bz) in a TRPV1 knockout mouse. Note there is no amiloride-insensitive response (i.e., no response to NaCl + Bz). Wildtype mice show an amiloride-insensitive NaCl response. This shows that the amiloride-insensitive response to NaCl depends on the expression of the TRPV1 gene.

2. Increases in temperature and vanilloid concentration, in turn, increase the response conductance (slope of the normalized CT response with voltage applied to the anterior lingual receptive field), that is, the taste receptor has ion channel characteristics *in situ*.
3. Vanilloids, external pH, and ATP lower the temperature threshold of the response.
4. A TRPV1 mRNA transcript common to several channels in the TRP receptor family was detected in rat fungiform TBCs (see also Liu, L. and Simon, S. A., 2001a; 2001b).
5. TRPV1 knockout mice lack an amiloride-insensitive NaCl CT response (see Figure 28) while control mice show an intact response.
6. Ethanol is an agonist of the amiloride-insensitive salt taste response (Lyall, V. *et al.*, 2005) similar to its agonist effect on cloned TRPV1 (Trevisani *et al.*, 2002).

These results suggest that the amiloride-insensitive nonselective cation salt taste receptor in the taste cells of fungiform papillae is a TRPV1 variant (TRPV1t). Two reasons indicating that TRPV1t differs from TRPV1 are as follows:

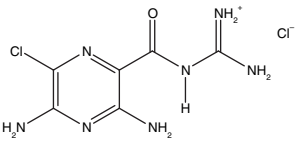
1. TRPV1t is constitutively active, while TRPV1 must be activated by temperature, pH, or vanilloids, and
2. Unlike TRPV1, TRPV1t is not affected by a drop in pH alone.

A vanilloid must be present for TRPV1t to show pH dependence. At present it is not known what structural differences between TRPV1t and TRPV1 account for these important functional differences. Also it is not known if TRPV1t accounts for the nonselective cation salt sensitivity in the glossopharyngeal nerve (i.e., whether or not TRPV1t is also present in circumvallate taste cells) (Figure 29).

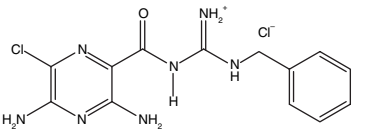
Differences in taste for salts with common cations. Why is NaCl a more potent salty stimulus than Na_2SO_4 or Na_3PO_4? Based on the foregoing discussion on the involvement of ENaC and TRPV1 in human salty taste, these three sodium salts should be equivalent in salty taste at common Na^+ concentration. However, this is not the case. NaCl is the most potent of the Na^+ salts and the diminished potencies of other Na^+ salts have long puzzled investigators in gustation research. An explanation for this apparent paradox began to emerge in the 1980s with the work of Harry Harper at Rockefeller University (1987), the author (JD) and co-workers at Virginia Commonwealth University (Ye, Q. *et al.*, 1991), and Sid Simon and co-workers at Duke University (Elliot, E. J. and Simon, S. A. 1990; Simon, S. A. *et al.*, 1993). It was proposed that NaCl and other Na^+ salts are able to passively diffuse through the tight junctions between TBCs and that, for salts with small counterions (e.g., Cl^-), both cation and anion are able to diffuse through the tight junctions at comparable rates. On the other hand, it was recognized that, while this is the case for small anions, for Na^+ salts with large anions, the rates of diffusion for the anions would be lower than that for the Na^+ ion and that therefore, for such salts, a hyperpolarizing field potential would be imposed on salt-sensitive TBCs which would inhibit the diffusion of Na^+ ions through ion channels in the apical membrane. The net result of this differential ionic diffusion is that Na^+ salts with large anions are expected to be less potent in salty taste than are salts with small anions and this is exactly what is observed.

4.02.6.2 Salty Tastant Structure–Activity Relationship

As already discussed, salt (i.e., NaCl) is the prototypical salty stimulus. However, for reasons that are now clear based on an understanding of the biochemistry of salty taste, many other salts exhibit



148 (Amiloride HCl)
$C_6H_9Cl_2N_7O$
$M = 266.09$



149 (Benzamil HCl)

$C_{16}H_{14}ClNO_2$
$M = 287.74$

Figure 29 Molecular tools employed in the study of salty taste.

salty taste. In general, salts exhibit multiple qualities of taste with sweet and bitter tastes being particularly common and even sourness observed for some (Shallenberger, R. S., 1993). Thus, as example, NaCl is perceived as sweet at low concentrations, salty and sweet at midrange concentrations, and only salty at higher concentrations. Bartoshuk L. M. *et al.* at Yale University (1978) noted that the observation of sweet taste for NaCl was protocol-dependent and required rinsing with water immediately before tasting the salt solution. KCl exhibits salty, sweet, and bitter qualities of taste. Thus, at low concentrations, KCl is weakly sweet and salty; at midrange concentrations, salty and weakly bitter; and at very high concentrations, only bitter. LiCl exhibits salty, sweet, and sour tastes. Thus, at low concentrations, LiCl is weakly sweet and salty, and at high concentrations, salty and weakly sour. K_2SO_4 exhibits salty, sweet, sour, and bitter tastes. Thus, at low concentrations, K_2SO_4 is sweet and bitter; at midrange concentrations, sweet, salty, and bitter; and at high concentrations, salty, bitter, and sour. As a bottom line, the presence of salty taste is common in salts of many different types even though the purest salty taste is exhibited by NaCl. The saltiness potencies for a number of salts were determined by von Skramlik E. (1926) and have been reviewed by Beets M. G. J. (1978). These potencies, recalculated so as to place them on a scale where 1 M NaCl is defined as having a potency of 1.00, are given in Figure 30 along with empirical formulas and formula weights.

4.03.1 Introduction

The sense of taste is vital to invertebrates. It helps them avoid noxious chemicals (White, P. R. and Chapman, R. F., 1990: Schoonhoven, L. M. *et al.*, 1992; Glendinning, J. I., 2002), select host plants and oviposition sites (Ma, W.-C. and Schoonhoven, L. M., 1973; Städler, E. *et al.*, 1995), and identify and discriminate food-related chemical stimuli (Dethier, V. G., 1976; Bernays, E. A. and Chapman, R. F., 1994; Glendinning, J. I. *et al.*, 2002). Taste also helps invertebrates coordinate digestion by stimulating salivation during meals (Friend, W. G. and Smith, J. J., 1971; Ribeiro, J. M. C. and Garcia, E. S., 1980; Watanabe, H. and Mizunami, M., 2006) and determining whether ingested food is directed to the midgut for digestion or the crop for storage (Schmidt, J. M. and Friend, W. G., 1991).

I will examine several features of taste function: (1) the organization of the peripheral and central gustatory system; (2) responses of taste cells to food-related stimuli; (3) central processing of gustatory input; (4) taste–mixture interactions; and (5) factors that modulate gustatory responses. I will limit discussion to insects because this is the invertebrate taxon whose gustatory system has been studied most extensively. Further, because this chapter focuses on the mechanisms by which taste modulates feeding of insects, I will not review comprehensively the literature on insect gustatory receptor (Gr) genes and associated signaling pathways. Detailed reviews of these topics can be found elsewhere (Clyne, P. J. *et al.*, 2000; Glendinning, J. I. *et al.*, 2000a; Ishimoto, H. *et al.*, 2000; Dahanukar, A. *et al.*, 2001; Scott, K. *et al.*, 2001; Robertson, H. M. *et al.*, 2003; Chyb, S., 2004; Hallem, E. A. *et al.*, 2006; Robertson, H. M. and Wanner, K. W., 2006).

4.03.2 Organization of the Peripheral Gustatory System

Insect taste cells are bipolar sensory neurons, which are housed in peg-shaped uniporous structures called basiconic sensilla (or taste sensilla) (Figure 1(a)). These taste sensilla can occur inside the oral cavity, on mouthpart appendages, and/or on the thorax, ovipositor, antennae, wing margins, and/or legs (Chapman, R. F., 1982; Hansen-Delkeskamp, E., 1992; Stocker, R. F., 1994; Schoonhoven, L. M. and van Loon, J. J. A., 2002; Shuichi Haupt, S., 2004). Owing to the external location of many taste sensilla, insects can taste foods simply by contacting them. The taste sensilla are innervated by the single, unbranched dendrites of two to six taste cells, which terminate near the distal tip of the sensillum (Figure 1(b)). The cell body of each cell is located

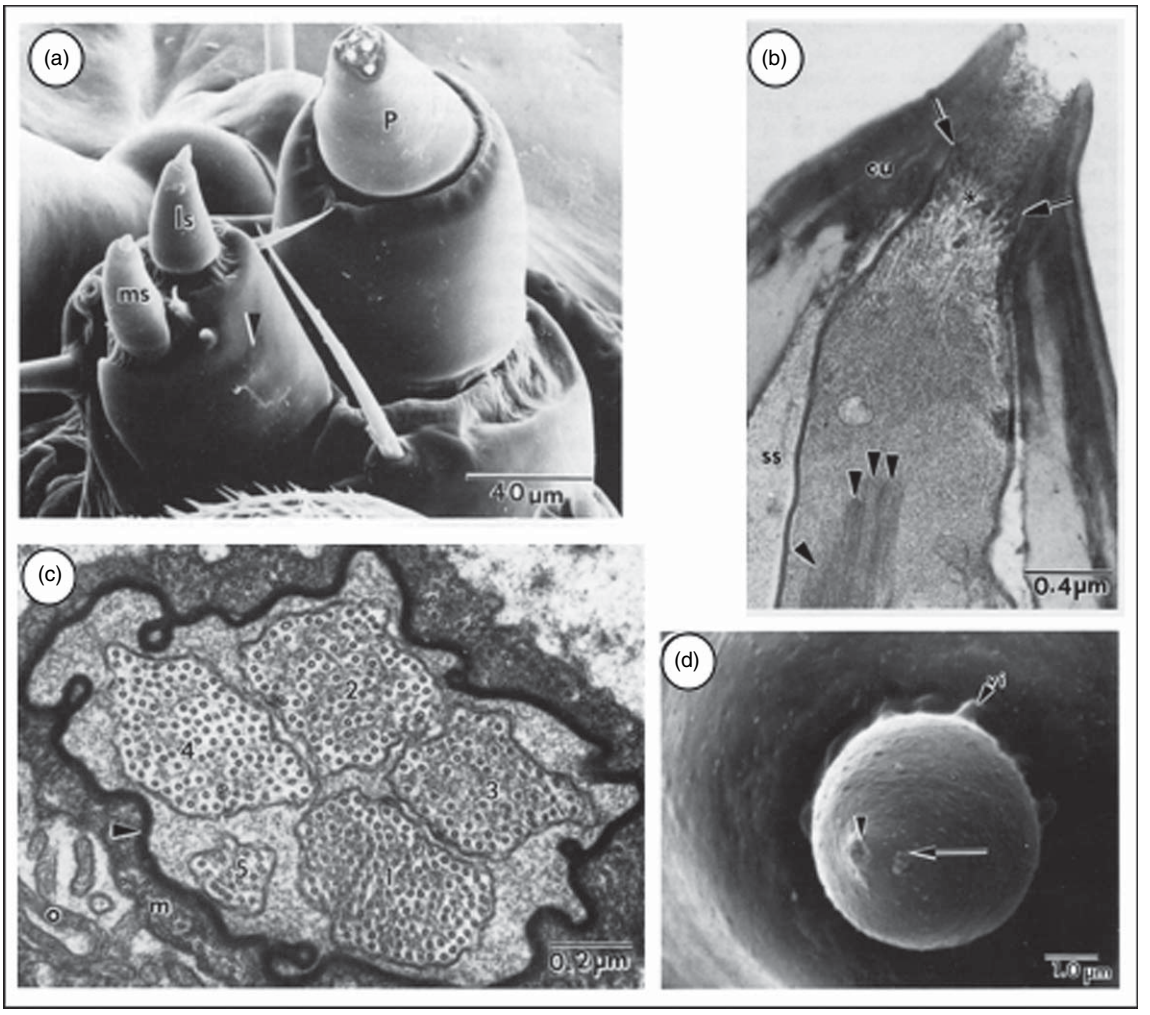

Figure 1 SEM micrographs of a taste sensillum from a caterpillar (*Mamestra configurata*, Lepidoptera: Noctuidae). (a) Left maxilla of caterpillar with lateral (*ls*) and medial (*ms*) styloconic sensilla, and a maxillary palp (*P*). (b) Longitudinal section of a lateral styloconic sensillum. At the top of the image, one can see the tip of the pore, which contains a plug of fenestrated fibirils (asterisk), and the dendritic sheath (arrows), which is fused with the cuticular wall of the sensillum. Four distal dendrites, each from different taste cells (arrowheads), can be seen near the bottom of the image; they are enclosed by the dendritic sheath. *cu*, cuticle; *ss*, sensillar sinus. (c) Proximal cross-section of a medial styloconic sensillum, showing four taste cells (*1–4*) and a mechanosensory neuron (*5*). All neurons are enclosed by a dendritic sheath (arrowhead), which is surrounded by a densely granulated intermediate sheath cell (m). *o*, outer sheath cell. (d) Apical view of the tip of a lateral styloconic sensillum with the terminal pore (arrowhead). These micrographs are from Shields, V. D. C. 1994. Ultrastructure of the uniporous sensilla on the galea of larval *Mamestra configurata* (Walker) (Lepidoptera: Noctuidae). Can. J. Zool. 72, 2016–2031.

near the base of the taste sensillum, and the axon extends directly to the central nervous system. In addition to taste cells, there is usually a single mechanosensory neuron in each taste sensillum (Figure 1(c)). The total number of taste sensilla per insect, and the distribution of these sensilla across the body surface, varies greatly among insect species (Chapman, R. F., 1982). Our ability to explore the membrane properties and intracellular signaling mechanisms of taste cells was increased by a recently developed method for isolating dissociated taste cells from pupal blowflies, *Phormia regina* (Murata, Y. *et al*., 2006).

Taste transduction begins when a chemical stimulus encounters the pore at the tip of a taste sensillum, diffuses through a mucopolysaccharide substance in the pore, and then dissolves into the fluid surrounding the dendrites (Figures 1(b) and 1(d)). This fluid (or receptor lymph) constitutes the outer ionic milieu for the dendritic process of each taste cell. Once the chemical stimulus encounters the distal dendritic membrane, it is thought to interact with specific receptor proteins and/or ionic channels, leading to changes in membrane conductance (Morita, H., 1992). The changes induce an inward current that flows through the transduction ion channels and down to the base of the dendritic process, where current outflow causes depolarization. While the receptor lymph provides some of the driving electromotive force for this taste cell current, most of the force appears to come from a +40 to +60 mV potential difference between the receptor lymph space and the blood (or hemolymph), called the transepithelial voltage (Thurm, U. and Küppers, J., 1980; Kijima, H. *et al*., 1995). The transepithelial voltage is established by electrogenic ion pumps located in the folded membrane of the tormogen and trichogen cells, which surround the taste cells.

4.03.3 Responses of Taste Cells to Food-Related Chemical Stimuli

Insect physiologists typically classify taste cells according to their best taste stimuli – that is, the stimuli that generate the strongest excitatory response. Accordingly, a taste cell that responds best to salts is called salt-sensitive, and a taste cell that responds best to compounds that humans describe as bitter is called bitter-sensitive. There are two caveats associated with this terminology. First, because most insect taste cells have been tested with only a limited number of taste stimuli, it is conceivable that the best stimulus for a taste cell has not yet been discovered. Second, the categorization of a taste cell as salt sensitive implies that stimulation of that taste cell generates a perception akin to saltiness in humans. At this point, we do not even know whether insects perceive distinct taste qualities like salty and sweet (see Section 4.03.5). For the sake of simplicity, I will use the conventional terminology for categorizing the taste cells, keeping in mind the above-stated caveats.

4.03.3.1 Bitter Compounds

Many of the compounds that taste bitter in humans also elicit an aversive response in insects (e.g., rapid cessation of feeding). Because virtually all naturally occurring poisons taste bitter to humans, the aversive response to these bitter compounds is thought to represent an evolved mechanism for limiting ingestion of toxic foods (Bate-Smith, E. C., 1972; Garcia, J. and Hankins, W. G., 1975; Brower, L. P., 1984; Brieskorn, C. H., 1990). The effectiveness of this taste-mediated poison detection system is limited by the fact that even though most poisons taste bitter, the opposite is not always true – that is, many compounds with a bitter taste are harmless (Bernays, E. A. and Chapman, R. F., 1987; Bernays, E. A., 1990; Rouseff, R. L., 1990; Bernays, E. A., 1991; Glendinning, J. I., 1994). Given that many nutritious plant tissues contain bitter compounds, insects (particularly herbivorous ones) would benefit from gustatory mechanisms that discriminate harmful and harmless bitter compounds.

Insects have several preingestive and postingestive mechanisms for detecting potentially toxic compounds in foods (Glendinning, J. I., 2002). The primary mechanism, however, is gustation. Insects have numerous taste cells that respond selectively to bitter compounds and elicit an aversive response when activated (Dethier, V. G., 1980; Schoonhoven, L. M. *et al*., 1992). These bitter-sensitive taste cells have been discovered in Orthopterans (White, P. R. and Chapman, R. F., 1990; Chapman, R. F. *et al*., 1991), Dipterans (Meunier, N. *et al*., 2003), Lepidopterans (Schoonhoven, L. M. *et al*., 1992), and some but not all Coleopterans (Mitchell, B. K., 1987; Messchemdorp, L. *et al*., 1998). To illustrate the response properties of bitter-sensitive taste cells, I will feature the caterpillar of *Manduca sexta* (Lepidoptera: Sphingidae). This insect has a total of 62 taste cells distributed across five classes of bilaterally paired taste sensilla: one lateral styloconic, one medial styloconic, one epipharyngeal, and five maxillary palp sensilla (Figure 2(a)).

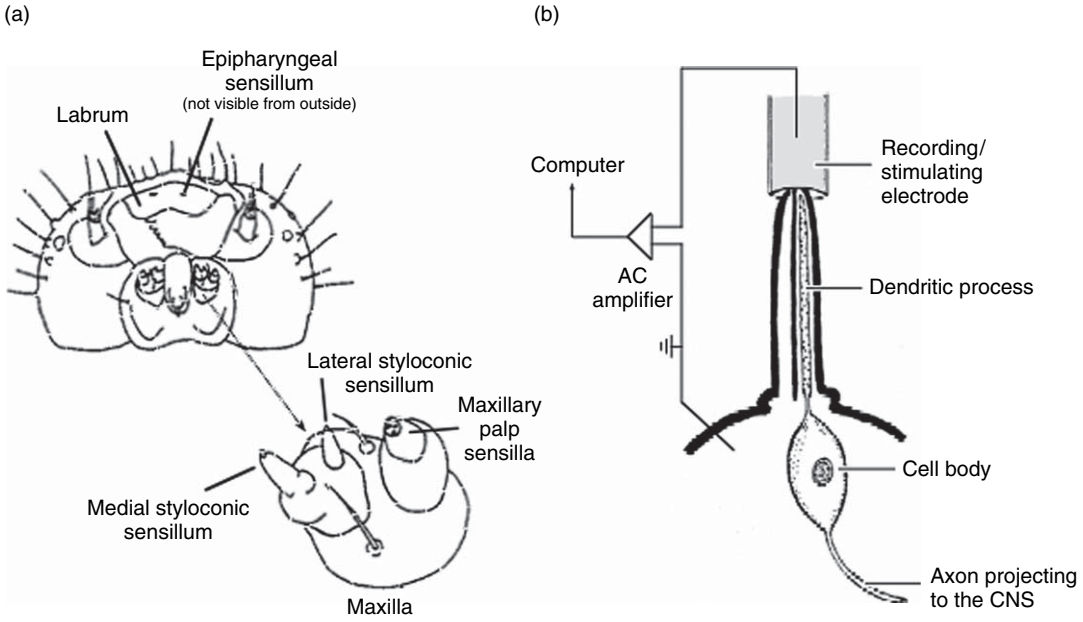

Figure 2 (a) Cartoon of the head of a *Manduca sexta* caterpillar, as viewed from below. An enlargement of the maxilla (indicated with an arrow) is provided to clarify the location of the medial and lateral styloconic sensilla. The epipharyngeal sensilla are located underneath the labrum, and thus are not visible in this diagram. (b) Illustration of the tip recording method, which was used to record excitatory responses of individual taste cells located within a taste sensillum. During a tip recording (Hodgson, E. S. *et al.*, 1955), the tip of a taste sensillum is inserted into the end of a glass recording/stimulating electrode, which is filled with a taste stimulus dissolved in an electrolyte solution (0.1 M KCl in deionized water). The taste stimulus solution diffuses through a pore in the tip of the sensillum and activates transduction mechanism(s) on the distal end of a taste cell's dendritic process; the electrode detects the ensuing action potentials. For clarity, only one taste cell is indicated. Note that the taste cell's axonal process projects directly to the central nervous system without synapsing. (a) This cartoon was adapted from Bernays, E. A. and Chapman, R. F. 1994. Host-Plant Selection by Phytophagous Insects. Chapman and Hall, their Figure 3.4.

Given that each taste sensillum contains one bitter-sensitive taste cell, *M. sexta* has a total of eight bilateral pairs of bitter-sensitive taste cells. Using the tip recording technique (Figure 2(b)), investigators have characterized the response of each bitter-sensitive taste cell to a structurally diverse range of substances that elicit immediate aversive responses: salicin, caffeine, aristolochic acid, *Canna* extract, and *Grindelia* extract (Figure 3). These recordings illustrate that the bitter-sensitive taste cell in the (1) epipharyngeal sensilla responds vigorously to salicin, caffeine, aristolochic acid, and *Canna* extract, (2) lateral styloconic sensilla responds vigorously to salicin, caffeine, aristolochic acid, and weakly to *Canna* extract, (3) medial styloconic sensilla responds vigorously to aristolochic acid and *Canna* extract, and weakly to caffeine and salicin, and (4) maxillary palp sensilla responds vigorously to *Grindelia* extract only (Glendinning, J. I. *et al.*, 2002). Behavioral studies have revealed that any bilateral pair of taste sensilla that responds vigorously to a particular bitter compound is also sufficient to mediate an aversive response to that compound (Glendinning, J. I. *et al.*, 1999a; 2002; Glendinning, J. I., unpublished data). Taken together, these studies show that *M. sexta* possesses a heterogeneous population of bitter-sensitive taste cells – some with identical molecular receptive ranges (MRRs), others with partially overlapping MRRs, and yet others with unique MRRs. The adaptive significance of this taste cell diversity is that it facilitates the detection and discrimination of bitter taste stimuli.

To determine whether two bitter taste stimuli (e.g., caffeine and salicin) activate the same taste cell, one can examine the neural response of a taste cell to each compound, both alone and in binary mixture. In Figure 4(a), we show the response of the bitter-sensitive taste cell in the lateral styloconic sensillum to caffeine alone, salicin alone, and the binary mixture of both. Because the binary mixture caused the bitter-sensitive taste cell to generate approximately twice as many spikes as did caffeine or salicin alone, we infer that caffeine and salicin activated the same bitter-sensitive taste cell. In Figure 4b, we show the response of the bitter-sensitive taste cell in the lateral

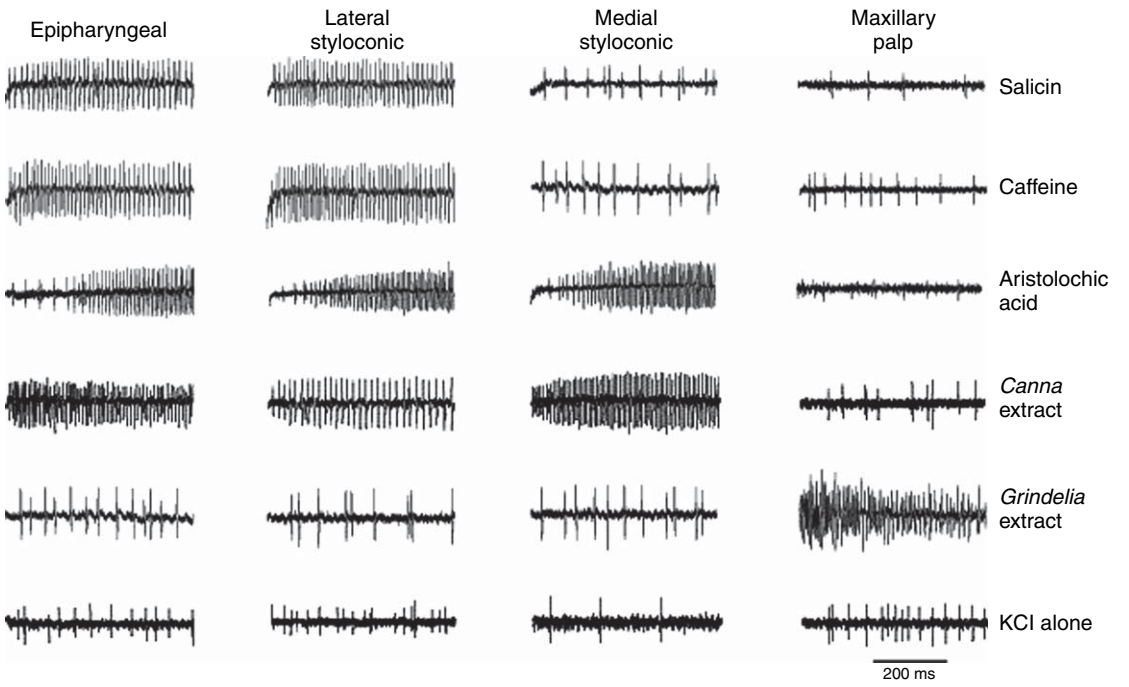

Figure 3 Typical excitatory responses of the four different classes of taste sensilla to five bitter taste stimuli: salicin, caffeine, aristolochic acid, *Canna* extract, and *Grindelia* extract (see Glendinning, J. I. *et al.*, 2002, for exact concentrations of each taste stimulus). The onset of stimulation occurred at the beginning of each trace, and each vertical line reflects the occurrence of an action potential. In most of the traces containing a large number of action potentials, there is a single taste cell (the bitter-sensitive taste cell) firing regularly, and another taste cell (the salt-sensitive taste cell) firing sporadically. The only exception is the multiunit response of the maxillary palp sensilla to the *Grindelia* extract, which probably contains action potentials from several bitter-sensitive taste cells. Because all bitter taste stimuli were presented in a 0.1 M KCl solution, we also show representative responses of each sensillum to the electrolyte solution alone for comparison (see bottom row of traces). Note that each bitter taste stimulus selectively activates bitter-sensitive taste cells in a subset of the taste sensilla (e.g., the *Grindelia* extract only stimulated bitter-sensitive taste cells in the maxillary palp). These traces are from Glendinning, J. I., Davis, A., and Ramaswamy, S. 2002. Contribution of different taste cells and signaling pathways to the discrimination of "bitter" taste stimuli by an insect. J. Neurosci. 22, 7281–7287.

styloconic sensillum to caffeine alone, *myo*-inositol alone, and the binary mixture of both. Because the response to the binary mixture consisted of two taste cells discharging out of phase with one another, and at the same rate as when each component was presented alone, we infer that each taste stimulus activated a different taste cell.

Several recent observations in adult *Drosophila* offer an explanation for why the bitter-sensitive taste cells in *Drosophila* (Meunier, N. *et al.*, 2003) and perhaps *M. sexta* (Figure 4) express distinct MRRs. The first observation is that the bitter-sensitive taste cells that express Gr66a (a presumed bitter taste receptor) respond to a diversity of bitter taste stimuli (Wang, Z. *et al.*, 2004; Marella, S. *et al.* 2006), and that silencing the Gr66a-expressing taste cells attenuates the aversive response to many bitter compounds (Wang, Z. *et al.*, 2004). The second observation is that knocking out the Gr66a receptor attenuates the responses of the bitter-sensitive taste cells to caffeine and theophylline, but spares responses to most other bitter taste stimuli (Moon, S. J. *et al.*, 2006). Taken together, these observations indicate (1) that there are many different bitter taste receptors, (2) that each receptor has a relatively narrow and distinct MRR; and (3) that each class of bitter-sensitive taste cell expresses different combinations of the receptors.

A final gustatory mechanism for limiting ingestion of bitter and potentially toxic compounds is activated when insects encounter foods that contain mixtures of nutrients and bitter compounds. For instance, the labellar taste sensilla in some flies appear to lack bitter-sensitive taste cells *per se*. However, the excitatory response of the sugar-, salt-, and water-sensitive taste cells to their respective ligands is inhibited by the presence of bitter compounds (Morita, H., 1959; Dethier, V. G. and Bowdan, E., 1989; Meunier, N. *et al.*, 2003). This inhibition effectively eliminates the gustatory input that would normally stimulate feeding

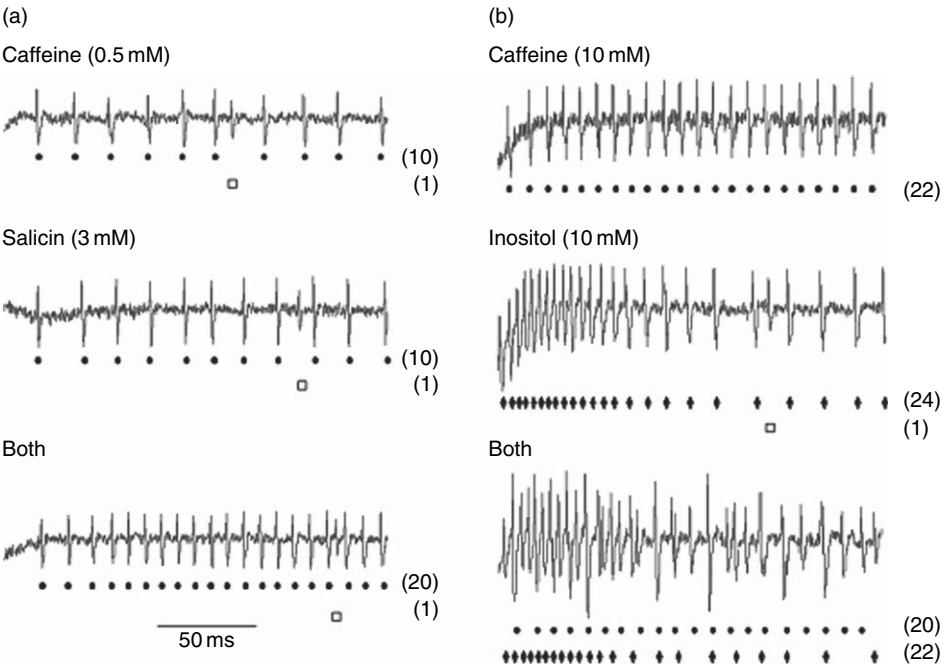

Figure 4 Excitatory responses of taste cells within a lateral styloconic sensillum of *Manduca sexta* caterpillars to single-component taste stimuli and binary mixtures. (a) Response of a bitter-sensitive taste cell to 0.5 mM caffeine alone, 3 mM salicin alone, and the binary mixture of both. Underneath each neural trace, we indicate the response of the bitter-sensitive taste cell (closed circle) and that of the salt-sensitive taste cell to the 0.1 mM KCl solvent (open square). We also indicate the total number of spikes assigned to each taste cell in parentheses. It is apparent that the bitter-sensitive taste cell generated twice as many spikes in response to the binary mixture than it did to either component alone. These traces are from Glendinning, J. I. and Hills, T. T. 1997. Electrophysiological evidence for two transduction pathways within a bittersensitive taste receptor. J. Neurophysiol. 78, 734–745. (b) Response of a bitter-sensitive taste cell to 10 mM caffeine, an inositol-sensitive taste cell to 10 mM *myo*-inositol alone, and both taste cells to the binary mixture of both taste stimuli. Underneath each neural trace, we indicate the response of the bitter-sensitive taste cell (closed circle), the response of the inositol-sensitive taste cell (closed diamonds), and the salt-sensitive taste cell (to the 0.1 mM KCl solvent) (open square). It is apparent that the bitter-sensitive taste cell and the inositol-sensitive taste cells each responded equally vigorously to their respective ligands, irrespective of whether they occurred alone or in binary mixture. Further, note that the response to the binary mixture contains two taste cells firing independently of one another; the unusually high-amplitude spikes reflect superpositions (i.e., instances when the two taste cells fired simultaneously). These traces are from Glendinning, J. I., Nelson, N., and Bernays, E. A. 2000b. How do inositol and glucose modulate feeding in *Manduca sexta* caterpillars? J. Exp. Biol. 203, 1299–1315.

(Dethier, V. G. and Bowdan, E., 1992). One limitation of this detection mechanism is that it is relatively nonselective – e.g., bitter stimuli that differ greatly in toxicity all produce a similar degree of inhibition (Dethier, V. G. and Bowdan, E., 1992).

4.03.3.2 Carbohydrates

Carbohydrates are strong feeding stimulants for many insects (Dethier, V. G., 1976; Bernays, E. A., 1985; Scheiner, R., 2004; Wang, Z. *et al.*, 2004). Most insects possess taste cells that respond selectively to saccharides (e.g., glucose, sucrose, fructose, and trehalose) and/or sugar alcohols (e.g., sorbitol, mannitol, and *myo*-inositol). Whereas Dipterans have carbohydrate-sensitive taste cells that respond both to saccharides and to sugar alcohols, most Lepidopterans have separate taste cells for saccharides and sugar alcohols (Dethier, V. G., 1976; Schoonhoven, L. M. and van Loon, J. J. A., 2002).

The taste system of adult *Drosophila* is notable because it contains the only deorphaned sweet taste receptor in insects: Gr5a. Using a combination of molecular, physiological, and behavioral approaches, investigators demonstrated that Gr5a is encoded by the *Gr5a* gene, and that it is tuned specifically to trehalose, an abundant metabolic byproduct of yeast and an important food source for *Drosophila* (Tanimura, T. *et al.*, 1982; 1988; Dahanukar, A. *et al.*, 2001; Ueno, K. *et al.*, 2001; Chyb, S. *et al.*, 2003; Inomata, N. *et al.*, 2004). Although mutation of Gr5a attenuated the responsiveness of the sugar-sensitive taste cells to trehalose, it had no impact on responsiveness of the same taste cells to

sucrose (Tanimura, T. *et al.*, 1982; 1988; Dahanukar, A. *et al.*, 2001; Ueno, K. *et al.*, 2001; Chyb, S. *et al.*, 2003; Inomata, N. *et al.*, 2004). In addition, two laboratories developed methods for selectively silencing the *Gr5a*-expressing taste cells in adult *Drosophila*; they did so by causing them to produce either tetanus (Thorne, N. *et al.*, 2004) or diphtheria (Wang, Z. *et al.*, 2004) toxin. Using the genetically modified flies, the laboratories demonstrated that flies expressing the toxins under the *Gr5a* driver showed an attenuated appetitive response to trehalose, but normal appetitive response to sucrose. Taken together, these molecular findings indicate that individual carbohydrate-sensitive taste cells express multiple taste receptors for sugars, each of which has a unique MRR. This inference is supported by electrophysiological studies showing that different classes of sensilla in *Drosophila* exhibit different response profiles for sugars (Hiroi, M. *et al.*, 2002).

Prior to the discovery of Gr5a, most work on sugar transduction focused on two hypothetical receptor sites: one that responds to pyranose sugars (e.g., glucose and sucrose) and another to furanose sugars (e.g., fructose) (Morita, H., 1992). The existence of these separate receptor sites was based on the following lines of evidence. Treating the sugar-sensitive taste cell with *p*-chloromercuribenzonate (a specific sulphydryl reagent) almost completely eliminated the response to pyranose sugars, but had no impact on the response to furanose sugars (Shimada, I. *et al.*, 1974). Conversely, treating the sugar-sensitive taste cell with amiloride abolished its response to furanose sugars, but not pyranose sugars (Liscia, A. *et al.*, 1997). Finally, Ozaki and her colleagues used affinity electrophoresis to isolate two putative taste receptor molecules; each of these proteins exhibited sugar-binding affinities and specificities that were consistent with separate pyranose- and furanose-binding sites (Ozaki, M. *et al.*, 1993). More work is needed to integrate these hypothetical receptor sites with our growing molecular understanding of insect gustation.

Based on sequence data from *Drosophila*, the 68 putative gustatory receptor genes (including *Gr5a*) are predicted to encode G-protein-coupled receptors (Robertson, H. M. *et al.*, 2003). In support of this prediction, several recent studies have reported that two G-protein subunits, Gsα and Gγ1, are both required for sugar detection in *Drosophila* (Ishimoto, H. *et al.*, 2005; Ueno, K. *et al.*, 2006). These G-protein subunits, in turn, appear to activate an IP_3 signaling pathway (Usui-Aoki, K. *et al.*, 2005). Other signaling molecules proposed to mediate sugar transduction include Gq-α (Seno, K. *et al.*, 2005b), nitric oxide (Schuppe, H. *et al.*, 2006), and calmodulin (Seno, K. *et al.*, 2005a).

4.03.3.3 Salts

Virtually all taste sensilla contain at least one salt-sensitive taste cell. Monovalent inorganic cations are the most effective stimulants for these taste cells (Dethier, V. G., 1976). Cations differ, however, in their stimulatory effectiveness (e.g., in the fleshfly, *Boettcherisca peregrina*, $Li^+ < Na^+ < Cs^+ < Rb^+ < K^+$) (den Otter, C. J., 1972). den Otter speculated that this order of stimulatory effectively does not vary as a function of ionic size or mobility because each cation interacts differentially with negative groups (probably phosphates) on the surface of the taste cells.

Flies show an appetitive response to low NaCl concentrations (5–10 mM) and aversive response to high NaCl concentrations ($\geq$500 mM) (Dethier, V. G., 1968; Hiroi, M. *et al.*, 2004). This concentration-dependent change in affective response to salts is thought to have evolved because low concentrations of salts satisfy nutritional needs, whereas higher concentrations threaten osmotic equilibrium. To explain the mechanistic basis of this behavior, Wang Z. *et al.* (2004) silenced the sugar-sensitive taste cells of *Drosophila* that express *Gr5a*. When these flies were offered a range of NaCl concentrations, they exhibited an attenuated appetitive response to the 5 mM concentration, but a normal aversive response to concentrations $\geq$500 mM. These latter findings, together with those of Hiroi M. *et al.* (2004), indicate that NaCl stimulates two different classes of taste cell – low concentrations stimulate a taste cell that elicits an appetitive response (presumably the so-called sugar-sensitive taste cell) and high concentrations stimulate a taste cell that elicits an aversive response (presumably a salt-sensitive taste cell).

In *Drosophila*, the aversive response to high (i.e., $\geq$500 mM) concentrations of NaCl is mediated in part by the *dpr* gene. This inference is based on behavioral studies with wildtype and *dpr*-knockout flies (Nakamura, M. *et al.*, 2002). The proboscis extension reflex was strongly inhibited by high NaCl concentrations in wildtype flies, but not in *dpr*-knockout flies. This *dpr* gene is thought to encode a protein with a single transmembrane domain and two Ig repeats, and to be expressed in a subset of taste cells (Nakamura, M. *et al.*, 2002).

An important, but unexplained, observation is that some insects can discriminate between different types of salts (Arms, K. *et al.*, 1974; Maes, F. W. and Bijpost,

S. C. A., 1979; Miyakawa, Y., 1981; 1982). In laboratory rats, the ability to discriminate Na^+ and K^+ salts appears to be mediated by differential input from Na^+-specific (amiloride-sensitive) and Na^+-nonspecific (amiloride-insensitive) cation channels (Spector, A. C. and Grill, H. J., 1992; Smith, D. V. *et al.*, 2000). The question of whether insects use a similar mechanism is unresolved. A recent study reported that *Drosophila* expresses a Na^+-nonspecific (amiloride-sensitive) cation channel (DEG/ENaC) in taste cells within the gustatory terminal organ (in larvae) and taste sensilla on the labellum, legs, and wing margins (in adults) (Liu, L. *et al.*, 2003). The inference that this channel is Na^+ nonspecific was based on the observation that disruption of the genes for DEG/ENaC (*ppk11* and *ppk19*) diminished behavioral and taste cell responsiveness to low (i.e., 10 mM) concentrations of both KCl and NaCl (Liu, L. *et al.*, 2003). Given that the gustatory response to 10 mM KCl in the genetically disrupted flies was still robust (i.e., ~50% of that observed in wildtype flies), it is likely that *Drosophila* also has a DEG/ENaC-independent mechanism for detecting salts. Accordingly, differential input from the DEG/ENaC-dependent and DEG/ENaC-independent mechanisms could mediate the discrimination of Na^+ and K^+ salts.

4.03.3.4 Amino Acids

Amino acids stimulate feeding in many species of insect, but the behavioral responsiveness to any given amino acid varies considerably across species (Bernays, E. A., 1985; Albert, P. J. and Parisella, S., 1988; Hirao, T. and Ariai, N., 1990; Kim, J. H. and Mullin, C. A., 1998). A positive feeding response to amino acids may serve two adaptive functions. First, amino acids could be used as a proxy for protein content of foods, given that plant tissues with relatively high protein concentrations should, on average, have relatively high concentrations of free amino acids. If so, then amino acid-sensitive taste cells could help insects identify protein-rich plant tissues. Second, because some amino acids (e.g., phenylalanine) are considered limiting nutrients for plant-feeding insects (Bernays, E. A., 1982), amino acid-sensitive taste cells could help the insect maintain nutritional homeostasis.

In caterpillars, amino acids often stimulate specific taste cells (Dethier, V. G., 1973; Schoonhoven, L. M. and van Loon, J. J. A., 2002). For example, two closely related species of *Pieris* possess an amino acid-sensitive taste cell that shows concentration-dependent increases in response to ecologically relevant concentrations of 12 L-amino acids (Dethier, V. G., 1973; van Loon, J. J. A. and van Eeuwijk, F. A., 1989). Other species of caterpillar (e.g., *Grammia geneura*) detect amino acids with multiple taste cells (Bernays, E. A. and Chapman, E. A., 2001b). One of the amino acid-sensitive taste cells in *G. geneura* is unusual in that it responds to a diverse array of phagostimulants present in the insect's preferred food plants, including seven amino acids, three sugars, and a secondary plant compound (catalpol, an iridoid glycoside) (Bernays, E. A. *et al.*, 2000).

Dipterans use a variety of gustatory mechanisms for detecting amino acids. On the one hand, the tsetse fly (*Flossina fuscipes fuscipes*) has an amino acid-sensitive taste cell that responds selectively and vigorously 11 of the 20 L-amino acids present in animal proteins (van der Goes van Naters, W. M. and den Otter, C. J., 1998). On the other hand, the blowfly (*P. regina*), fleshfly (*B. peregrina*), and hoverfly (*Eristalis tenax*) all lack taste cells that respond to amino acids (Wolbarsht, M. L. and Hanson, F. E., 1965; Shiraishi, A. and Kuwabara, M., 1970; Goldrich, N. R., 1973; Wacht, S. *et al.*, 2000). Instead, these flies detect amino acids in more complex ways. For instance, when the labellar sensilla of blowflies and fleshflies were stimulated with each of 19 L-amino acids, the ensuing neural response fell into one of four categories. The amino acids (1) inhibited the excitatory response of all taste cells (aspartic acid, glutamic acid, histidine, arginine, and lysine); (2) stimulated the salt-sensitive taste cells (proline and hydroxyproline); (3) stimulated the sugar-sensitive taste cell (valine, leucine, isoleucine, methionine, phenylalanine, and tryptophan); or (4) failed to stimulate or inhibit any taste cell (glycine, alanine, serine, threonine, cysteine, and tyrosine) (Shiraishi, A. and Kuwabara, M., 1970; Goldrich, N. R., 1973). The behavioral significance of these neural responses is unclear because the same taste stimuli fail to elicit normal appetitive responses – that is, proboscis extension reflexes (Wolbarsht, M. L. and Hanson, F. E., 1965).

4.03.3.5 Acids

In humans, acids elicit the perception of sourness. Although organic acids tend to be more sour than inorganic acids (at the same pH), the intensity of sourness generally increases with proton concentration. Little is known about the behavioral responses of insects to low pH foods, however. There is one report showing that ascorbic acid stimulates feeding in *Pieris*

brassicae caterpillars, but only when it is presented in binary mixture with sucrose (Ma, W.-C., 1972).

Organic acids occur in all plant tissues, and their concentrations can reach levels over 100 mM (e.g., citric acid from the Krebs cycle) (Harborne, J. B., 1973). Another nutritionally significant organic acid, ascorbic acid, occurs in plant tissues at concentrations of 1–10 mM (Schultz, J. C. and Lechowicz, M. J., 1986). The fact that ascorbic acid is an essential vitamin for most herbivorous insects may explain why caterpillars show an appetitive response to ascorbic acid when it co-occurs with sugars. On the other hand, the fact that acidic substances can be toxic and/or depress pH of the midgut may explain why many insects display an aversive response to highly acidic foods.

Ground beetles (Coleoptera, Carabidae) are the only known taxon of insects with taste cells that show pH-dependent changes in excitatory response. In these taste cells, the higher the pH, the higher the firing rate (Millius, M. *et al.*, 2006). For most other taxa of insects, acids appear to play a modulatory role – that is, alter the responsiveness of specific taste cells to their best stimuli. For example, at low concentrations, acids inhibit the responsiveness of salt-sensitive taste cells, whereas at higher concentrations, they inhibit the responsiveness of sugar- and inositol-sensitive taste cells and stimulate bitter-sensitive taste cells (Dethier, V. G. and Kuch, J. H., 1971; Bernays, E. A. *et al.*, 1998). These modulatory effects of acids are due to pH and not to specific effects of any particular acidic compound.

4.03.3.6 Miscellaneous Compounds

In addition to the taste stimuli described above, insect taste cells have been found to respond to chemicals not traditionally studied by taste physiologists. Below are four examples. First, the sugar-sensitive taste cells of blood-feeding insects (e.g., the fleshfly, *B. peregrina*) discharge in response to nucleotides in the blood of hosts (e.g., ADP and GDP) (Furuyama, A. *et al.*, 1999). Second, several herbivorous insects possess taste cells that respond to phytoecdysteroids in plant tissues (Ma, W.-C., 1969; Tanaka, Y. *et al.*, 1994; Marion-Poll, F. and Descoins, C., 2002; Calas, D. *et al.*, 2007). Stimulation of these taste cells elicits an aversive response. This response is thought to have evolved because phytoecdysteroids are found in about 6% of all land plant species, and their consumption can interfere with ecdysis. Third, some plant compounds, which are bitter and poisonous to mammals, actually stimulate feeding in herbivorous insects. For example, several species of insect, which depend on pyrrolizidine alkaloids (PAs) for reproduction and chemical defense against predators, possess taste cells specifically tuned to PAs (Bernays, E. A. *et al.*, 2002; 2003). These PA-sensitive taste cells are thought to facilitate the location and consumption of PA-containing plants. Fourth, given the ease at which insects desiccate, it is not surprising that they have evolved taste cells tuned to water (Dethier, V. G., 1976). A recent study identified water-sensitive taste cells in adult *Drosophila* and showed that these taste cells project to a region of the subesophageal ganglion (SOG) that is distinct from that of the sugar- and bitter-sensitive taste cells (Inoshita, T. and Tanimura, T., 2006).

4.03.4 Organization of the Central Gustatory System

The SOG is considered the first relay center for taste processing because it is where the axons of most taste cells terminate (Kent, K. S. and Hildebrand, J. G., 1987; Mitchell, B. K. and Itagaki, H., 1992; Stocker, R. F., 1994; Mitchell, B. K. *et al.*, 1999; Thorne, N. *et al.*, 2004; Wang, Z. *et al.*, 2004). Exceptions to this pattern include instances where (1) taste cells in the legs of Orthopterans project to thoracic ganglia (Rogers, S. M. and Newland, P. L., 2002); and (2) a subpopulation of taste cells in the mouthpart sensilla of Lepidopterans project to the tritocerebrum (Kent, K. S. and Hildebrand, J. G., 1987; Jørgensen, K. *et al.*, 2006).

Several lines of evidence indicate that taste cells can directly activate feeding control circuits in the SOG. First, taste cell axons intermingle with (or occur in close apposition to) arborizations from the mouthpart motor neurons (Altman, J. S. and Kien, J., 1987). Second, some SOG interneurons have branches that occur in neuropil with both sensory and motor terminals (Altman, S. and Kien, J., 1987). Third, stimulating taste cells with plant extracts directly modulates the output of the mouthpart motor neurons (Griss, C. *et al.*, 1991). In addition to exerting effects within the SOG, afferent gustatory information appears to be relayed via the subesophageal-calycal tract to higher processing centers in the calyces of the mushroom body, which are important neuropils for learning and memory (Schröter, U. and Menzel, R., 2003).

To gain insight into the organization of the SOG, investigators initially used anatomical and cobalt-filling techniques, together with activity-dependent

staining of single neurons, to determine the projection sites of axons from taste cells. These studies revealed that taste cells from different gustatory organs, different taste sensilla, or even the same sensillum can project to spatially distinct regions of the SOG (Kent, K. S. and Hildebrand, J. G., 1987; Shanbhag, S. R. and Singh, R. N., 1992; Stocker, R. F., 1994; Pollack, G. S. and Balakrishnan, R., 1997; Jørgensen, K. *et al.*, 2006).

Using molecular tools, investigators have been able to define more precisely the central projection patterns of taste cells. For example, work in *Drosophila* has shown that taste receptor expression can be used to characterize axonal projections from different classes of taste cell. Several investigators have shown that axonal projections to the SOG are segregated spatially according to both taste cell type (e.g., sugar sensitive versus bitter sensitive) and gustatory organ (proboscis, mouthparts, and legs) (Figure 5) (Thorne, N. *et al.*, 2004; Wang, Z. *et al.*, 2004; Inoshita, T. and Tanimura, T., 2006). These findings reveal that the SOG is organized according to a chemotopic and somatotopic organizational plan – i.e., the spatial pattern of activation reflects both the class of taste cell that was stimulated and the location of the taste stimulus on the body.

4.03.5 Central Processing of Gustatory Input

Mammals categorize taste stimuli according to three orthogonal dimensions: intensity, hedonics, and quality (Grill, H. J. and Berridge, K. C., 1985; Spector, A. C.,

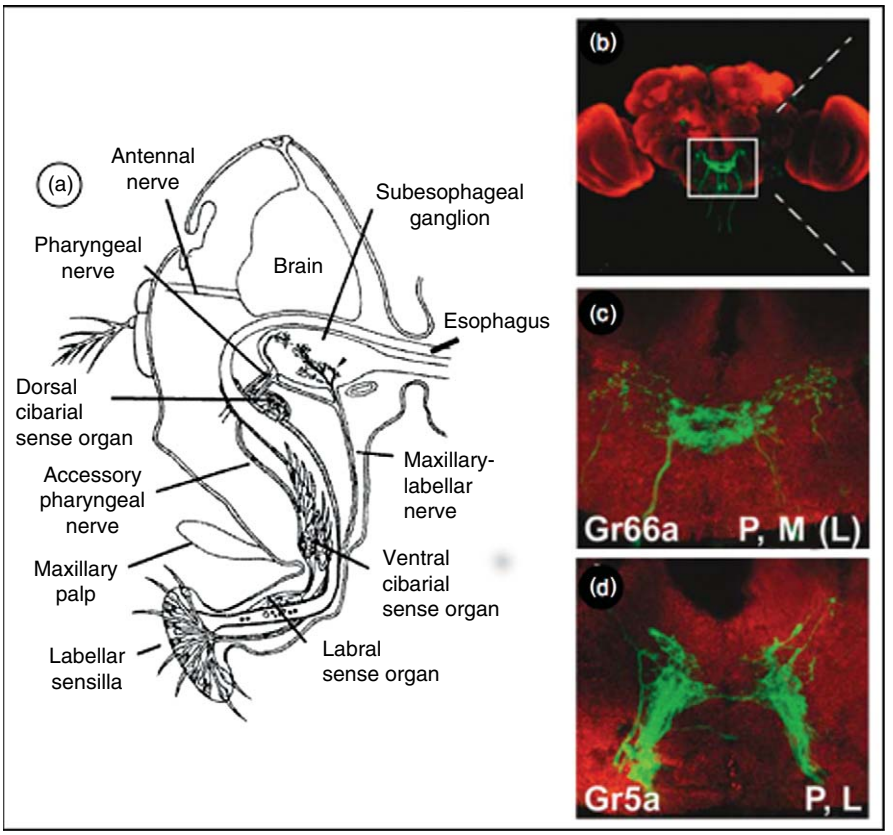

Figure 5 (a) Ultrastructure of the head, feeding apparatus, and central nervous system of an adult fruit fly *Drosophila melanogaster* (from Stocker, R. F. and Schorderet, M. 1981. Cobalt filling of sensory projections from internal and external mouthparts in *Drosophila*. Cell Tissue Res. 216, 513–523). (b) A whole-mount of the brain of *D. melanogaster*, showing axonal projects from taste cells (labeled with anti-GFP immunohistochemistry). The white box indicates the region of the SOG depicted in (c)–(d). (c–d) The green axons are from taste cells expressing a presumed bitter taste receptor, Gr66a (c), and the trehalose taste receptor, Gr5a (d). It is notable that the projection sites for taste cells expressing Gr66a are spatially distinct from those expressing Gr5a. (b)–(d) Are from Wang, Z., Singhvi, A., Kong, P., and Scott, K. 2004. Taste representations in the *Drosophila* brain. Cell 117, 981–991.

2000). Do insects use these three taste dimensions as well? Behavioral studies provide clear support for use of the intensity and hedonic dimensions. With regard to intensity, there are several reports of insects (1) exhibiting concentration-dependent changes in taste-mediated behavioral responsiveness to specific taste stimuli (Dethier, V. G., 1968; Bowdan, E., 1995; Glendinning, J. I. and Gonzalez, N. A., 1995; Glendinning, J. I. *et al*., 1999a; Wang, Z. *et al*., 2004), and (2) discriminating different intensities (i.e., concentrations) of salts in a classical conditioning paradigm (Maes, F. W. and Bijpost, S. C. A., 1979). With regard to hedonics, there are numerous reports of insects showing a taste-mediated preference or aversion to chemical stimuli (Harley, K. L. S. and Thorsteinson, A. J., 1967; Dethier, V. G., 1968; 1976; Bernays, E. A. and Chapman, R. F., 1994; Bowdan, E., 1995; Glendinning, J. I. and Gonzalez, N. A., 1995; Glendinning, J. I. *et al*., 1999a; Wang, Z. *et al*., 2004). The question of whether insects categorize taste stimuli into different qualities, however, has not been examined systematically.

To demonstrate that taste stimuli are grouped into different qualities (e.g., sweet, salty, sour, bitter, and umami), one cannot simply observe unconditioned behavioral responses. This is because taste stimuli with different taste qualities can elicit similar behavioral responses (Spector, A. C., 2000). For example, in many insects, high concentrations of bitter or salty taste stimuli elicit an aversive response. In the mammal literature, the most commonly used paradigm for determining whether two stimuli elicit distinct taste qualities is the conditioned taste aversion (CTA) (Frank, M. E. and Nowlis, G. H., 1989; Wiggins, L. L. *et al*., 1989). In brief, one creates a CTA to a reference taste stimulus (e.g., quinine), and then asks whether the CTA generalizes to an isostimulatory concentration of another taste stimulus (e.g., NaCl). If the animal does not generalize the CTA, then one infers that the two taste stimuli have distinct taste qualities. On the other hand, if the animal does generalize the CTA, then one infers that the animal could not distinguish the two taste stimuli because they produce a common taste quality. While this CTA-generalization procedure has been used successfully in mammals, I am unaware of its application to insects. Given that insects are capable of forming CTAs (Gelperin, A., 1968; Lee, J. C. and Bernays, E. A., 1990), the CTA-generalization paradigm should provide a powerful tool for analyzing taste qualities in insects. If not, then an alternative approach would be to generate a conditioned taste preference (CTP) to one taste stimulus (Gerber, B. *et al*., 2004; Hendel, T. *et al*., 2005.), and then test for generalization of the CTP to another taste stimulus.

The question of how gustatory input is processed is complicated by the observation that many taste-responsive neurons in the SOG respond to tactile input (Mitchell, B. K. and Itagaki, H., 1992; Rogers, S. M. and Simpson, S. J., 1999). This tactile input is derived from touch receptors within the taste sensilla, which generate action potentials when the taste sensilla are bent (e.g., while contacting food items). Even though tactile input from taste sensilla may provide critical proprioceptive feedback about the position of the chemosensilla relative to a food item, one might predict that the convergence of taste and tactile input on the same SOG interneurons would complicate taste processing. The insect may be able to reduce the contribution of tactile input, however, by limiting the strength of contact between the taste sensilla and food item (Rogers, S. M. and Simpson, S. J., 1999).

A recent study of *Drosophila* larvae revealed the power of applying molecular tools to the study of central taste processing (Melcher, C. and Pankratz, M. J., 2005). Using microarray analysis, the authors discovered a neuropeptide gene, *hugin* (*hug*), which is expressed in about 20 interneurons within the SOG. The axons of these interneurons project to the pharyngeal muscles, the ring gland (a central neuroendocrine organ), and the protocerebrum. On the other hand, the dendrites of the *hug*-expressing neurons receive input from taste cells and pharyngeal chemosensory cells. When the authors blocked synaptic transmission of the *hug*-expressing neurons, they altered the initiation of feeding in the larvae. Taken together, these observations suggest that the *hug*-expressing neurons are part of a neural circuit that modulates taste-mediated feeding responses.

4.03.5.1 Coding Mechanisms

The nature of the neural code for insect taste is unresolved. As in mammalian systems, there is debate over the relative importance of three different coding frameworks: labeled lines, ensemble (i.e., across fiber) patterns, and temporal patterns of spiking. The labeled-line framework hypothesizes that tastant identity is represented by neural activity in a limited subset of gustatory neurons. According to this model, activation of the sugar-sensitive taste cells would stimulate neural circuits within the SOG that initiate biting, whereas activation of a bitter-sensitive taste

cell would inhibit the same neural circuits. Further, the behavioral response to a mixture of sugars and bitter taste stimuli should reflect the algebraic sum of the inputs from the carbohydrate- and bitter-sensitive taste cells, respectively (Schoonhoven, L. M. and Blom, F., 1988; Simmonds, M. S. J. and Blaney, W. M., 1991). A recent study (Marella, S. *et al.*, 2006) provided strong evidence that *Drosophila* uses labeled-line coding. The investigators genetically engineered two types of flies (e.g., A and B). Type A flies expressed a capsaicin receptor (VR1E600K) in the taste cells that express the Gr5a receptor (i.e., the sugar-sensitive taste cells), whereas type B flies expressed the same capsaicin receptor in taste cells that express the Gr66a receptor (i.e., the bitter-sensitive taste cells). Then, they showed that when offered a capsaicin-treated agar, the type A flies exhibited an appetitive response, while the type B flies exhibited an aversive response. This remarkable result shows that the nature of an insect's ingestive response to a chemical stimulus (i.e., appetitive or aversive) is not determined by the chemical itself; rather, it is determined by the specific class of taste cell (or labeled line) that is activated.

The ensemble coding framework hypothesizes that tastant identity is represented by the spatial pattern of activity across large populations of neurons (Schoonhoven, L. M. *et al.*, 1992; Smith, D. V. *et al.*, 2000). According to this framework, discriminable taste stimuli should each elicit different ensemble patterns (i.e., different magnitudes of discharge across the population of taste cells). Ensemble coding was evaluated in a study that sought to determine how *M. sexta* caterpillars discriminate the taste of three different host plants (Dethier, V. G. and Crnjar, R. M., 1982). After evaluating the three potential coding frameworks, the authors concluded that ensemble pattern provided the most parsimonious discrimination mechanism. Elsewhere, another study (Glendinning, J. I. *et al.*, 2002) demonstrated that *M. sexta* uses ensemble coding to discriminate between two aversive taste stimuli (salicin and *Grindelia* leaf extract), which activate different classes of bitter-sensitive taste cell.

While the labeled-line and ensemble coding frameworks focus on which neurons are activated within the gustatory neuraxis, the temporal coding framework focuses on how neurons are activated. The latter framework hypothesizes that tastant identity is represented by the precise temporal pattern of spiking within a neuron or across populations of neurons (Dethier, V. G. and Crnjar, R. M., 1982; Katz, D. B. *et al.*, 2002; Katz, D. B., 2005). Support for this hypothesis comes from a recent study of *M. sexta* caterpillars (Glendinning, J. I. *et al.*, 2006). Several of the bitter-sensitive taste cells in this caterpillar generate a decelerating temporal pattern of spiking when stimulated by caffeine and salicin, and an accelerating temporal pattern of spiking when stimulated by aristolochic acid. The authors showed that the caterpillars use the distinct temporal patterns of spiking generated by salicin and aristolochic acid as a basis for discrimination.

It is important to emphasize two caveats associated with the coding frameworks discussed above. First, the three frameworks are not mutually exclusive. In fact, they probably function together in a complimentary manner within the same insect, as suggested by Dethier V. G. and Crnjar R. M. (1982). Second, given the profound effects of taste–mixture interactions, physiological state, and experience on responsiveness of individual taste cells to their respective ligands (see Sections 4.03.6 and 4.03.7), central processing of the peripheral signal is probably more dynamic than hitherto appreciated.

4.03.6 Taste–Mixture Interactions

Most studies of insect taste focus on single-component stimuli. While this approach offers many experimental advantages, it has limited ecological relevance because most foods contain complex mixtures of taste stimuli. Below I discuss our current (and admittedly, incomplete) understanding of taste–mixture interactions.

Four different types of taste–mixture interactions have been described in the peripheral taste system of insects. First, some compounds fail to produce any stimulatory effects on their own, but nevertheless inhibit the response of specific taste cells to their best stimulus (Dethier, V. G. and Bowdan, E., 1989; Bernays, E. A. and Chapman, R. F., 2000). Second, complex mixtures of taste stimuli can produce inhibitory effects in which the total number of impulses generated by the mixture is less than the algebraic sum of impulses generated by each of the mixture components alone (Ishikawa, S., 1967; Schoonhoven, L. M., 1978; Bernays, E. A. and Chapman, R. F., 2001a). Third, activation of one taste cell can inhibit the response of another taste cell to its own best stimulus (Mitchell, B. K., 1987; Blaney, W. M. and Simmonds, M. S. J., 1990; Chapman, R. F. *et al.*, 1991;

Schoonhoven, L. M. *et al*., 1992; Shields, V. D. C. and Mitchell, B. K., 1995; Bernays, E. A. and Chapman, R. F., 2000). Fourth, taste mixtures can produce synergistic interactions – for example, simultaneous activation of two taste cells by their respective best stimuli can cause a single taste cell to discharge at a rate substantially higher than expected based on tests with each taste stimulus alone (Dethier, V. G., 1971; Dethier, V. G. and Kuch, J. H., 1971).

The mechanistic basis for peripheral mixture interactions is unclear. Some interactions may involve direct electrical communication between taste cells via gap junctions. In support of this suggestion, two studies have found what appear to be gap junctions between taste cells in flies (Isidoro, N. *et al*., 1993) and thermo/hygrosensory neurons in a moth (Steinbrecht, R. A., 1989). However, another study failed to observe any evidence for gap junctions between taste cells in a caterpillar (Shields, V. D. C., 1994). A second possibility is that stimulation of one taste cell influences the responsiveness of others within the same taste sensillum through centrifugal feedback from the central nervous system. A third possibility is that activity in one taste cell may inhibit activity in a nearby cell through an ephaptic interaction (Jefferys, J. G., 1995; Bokil, H. *et al*., 2001). A final possibility is that that a single taste cell could express two signaling pathways, and activation of one pathway inhibits (or enhances) the response of the other (Dethier, V. G. and Bowdan, E., 1989).

Taste–mixture interactions have also been observed in the central gustatory system. For instance, caffeine normally elicits a taste-mediated aversive response in *M. sexta* caterpillars (Glendinning, J. I. *et al*., 1999a). However, when caffeine is presented in binary mixture with *myo*-inositol, the aversive response is completely attenuated (Glendinning, J. I. *et al*., 2000b). Recordings from the peripheral taste system of this insect revealed that the bitter-sensitive taste cells exhibited the same response to caffeine, irrespective of whether the caffeine was presented alone or in binary mixture with *myo*-inositol; likewise, the inositol-sensitive taste cells exhibited the same response to *myo*-inositol, irrespective of whether the myo-inositol was presented alone or in binary mixture with caffeine (Glendinning, J. I. *et al*., 2000b). The most parsimonious interpretation of these findings is that input from the inositol-sensitive taste cells inhibited the neural circuit in the central nervous system that mediates the aversive response to caffeine.

4.03.7 Factors that Modulate Gustatory Responsiveness

One of the most remarkable features of the insect taste system is its plasticity. To illustrate this point, I discuss below four factors known to increase (or decrease) the responsiveness of the gustatory system to specific taste stimuli.

4.03.7.1 Physical Changes in Taste Sensilla

In order for a chemical to stimulate a taste cell, it must first diffuse through the pore at the tip of a taste sensillum (see Figure 1). Although this terminal pore remains permanently open in many insect species, it opens and closes in Orthopterans (Bernays, E. A. *et al*., 1972). The functional significance of terminal pore closure was revealed by a series of experiments in locusts, *Locusta migratoria* (Bernays, E. A. and Chapman, R. F., 1972). When the foregut of the locust becomes distended (e.g., after a meal), stretch receptors in the wall of the foregut are activated and send afferent signals to the brain via the posterior pharyngeal nerves and frontal connectives. These afferent signals stimulate the release of a diuretic hormone from the corpora cardiaca, which in turn cause pore closure in many of the taste sensilla. The functional effect of terminal pore closure is that it contributes to meal termination by eliminating phagostimulatory input from the peripheral taste system.

4.03.7.2 Nutrient Levels in Blood

Several investigators have discovered that changes in the concentration of specific nutrients in the blood (e.g., amino acids or trehalose) directly modulate the responsiveness of taste cells in grasshoppers and caterpillars to the same chemicals (Simmonds, M. S. J. *et al*., 1992; Simpson, S. J. and Simpson, C. L., 1992; Bernays, E. A. *et al*., 2004). In locusts, when blood levels of amino acids are low and sugars high, the responsiveness of the taste cells to amino acids is high and that to sugars is low (Simpson, S. J. and Simpson, C. L., 1992). In contrast, when blood levels of amino acids are high and sugars low, the responsiveness of the taste cells to amino acids is low and that to sugars is high. Because these modulatory effects of blood nutrients on taste cell responsiveness occur in the absence of neural or humoral links between the central nervous system and taste cells, they must be mediated peripherally. A recent study indicates that nutrient

levels in the blood may modulate secretion of nitric oxide from glandular cells surrounding the taste cells, which in turn modulates the responsiveness of taste cells to their respective ligands (Schuppe, H. *et al.*, 2006).

4.03.7.3 Dietary Experience Effects

When insects are exposed repeatedly to the same taste stimulus (e.g., within and across successive meals), the responsiveness of their gustatory system to these stimuli can increase or decrease. The time scale over which these changes occur varies from seconds to days. Below, I discuss four ways that dietary experience modifies taste.

4.03.7.3.1 Short-term sensory adaptation

A common feature of all sensory receptor cells is that their firing rate diminishes over time in response to continuous stimulation (i.e., adapts), but recovers rapidly upon removal of the stimulus (i.e., disadapts). Adaptation and disadaptation occur over a period of milliseconds to seconds. To illustrate this process, we show adaptation curves for two taste cells in the lateral styloconic sensillum of *M. sexta* caterpillars (Figure 6). It is apparent that the response (as indicated by impulses per 100 ms) of the inositol-sensitive taste cell to 1 mM *myo*-inositol diminished by >50% over 500 ms, whereas that of the bitter-sensitive taste cell to 5 mM caffeine diminished by <10% over the same time period.

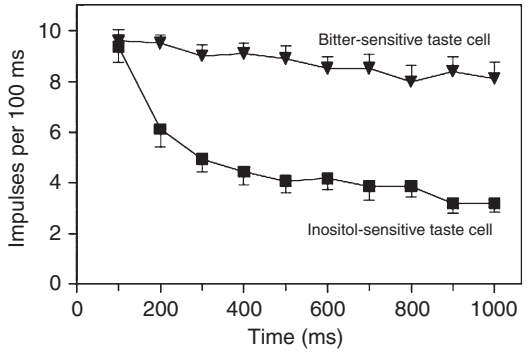

Figure 6 Adaptation rates of three different taste cells in the lateral styloconic sensillum of *Manduca sexta* caterpillars (as indicated by the number of spikes during each of 10 consecutive 100 ms bins). We show adaptation of the bitter-sensitive taste cell to 5 mM caffeine and the inositol-sensitive taste cell to 1 mM *myo*-inositol. Symbols indicate mean ±SE; $N = 10$ sensilla, each from different fifth instar caterpillars. These data are from Glendinning, J. I., Nelson, N., and Bernays, E. A. 2000b. How do inositol and glucose modulate feeding in *Manduca sexta* caterpillars? J. Exp. Biol. 203, 1299–1315.

The finding that bitter-sensitive taste cells are more resistant to adaptation than nutrient-sensitive taste cells has been reported for other insects as well (Schoonhoven, L. M., 1977). From a functional standpoint, this finding indicates that the relative amount of afferent input from different taste cells during a meal may not be constant, with the relative amount of input from the bitter-sensitive taste cells increasing over time. The extent to which these adaptation processes contribute to feeding during a meal is unclear, however, because insect gustatory organs do not remain in continuous contact with foods throughout a meal. Some gustatory organs make a series of drumming movements, resulting in intermittent contacts lasting only 100–200 ms (Blaney, W. M. and Duckett, A. M., 1975; Devitt, B. D. and Smith, J. J. B., 1985). These drumming movements could serve to minimize the effects of short-term adaptation in the taste cells and effectively increase the level of sensory input from taste cells over time (Blaney, W. M. and Duckett, A. M., 1975).

4.03.7.3.2 Habituation

When an animal is presented with a stimulus repeatedly across a sequence of trials, its responsiveness to that stimulus usually wanes (Hinde, R. A., 1970). This phenomenon is referred to as habituation if it meets several criteria – for example, it must be mediated centrally, recover spontaneously, generalize to related stimuli, and develop more readily in response to weak than intense stimuli (Thompson, R. F. and Spencer, W. A., 1966). For instance, fruit flies and bees normally exhibit a proboscis extension reflex for 5% sucrose, but this reflex extinguishes following 20 consecutive stimulations within a 5 min period (Duerr, J. S. and Quinn, W. G., 1982; Braun, G. and Bicker, G., 1992; Scheiner, R., 2004; Scheiner, R. *et al.*, 2004). This exposure-induced response decrement for sucrose was considered habituation because it met at least two of Thompson and Spencer's habituation criteria.

4.03.7.3.3 Long-term adaptation

When herbivorous insects are offered a diet containing an unpalatable but harmless compound as their only source of water and nutrients, they will usually sample the diet repeatedly. After ~24 h of such sampling, the insects eventually adapt their aversive response. This long-term adaptation phenomenon has been reported in several species of herbivorous

insect (Jermy, T. *et al.*, 1982; Simmonds, M. S. J. and Blaney, W. M., 1983; Szentesi, A. and Bernays, E. A., 1984; Blaney, W. M. and Simmonds, M. S. J., 1987; Usher, B. F. *et al.*, 1988; Glendinning, J. I. and Gonzalez, N. A., 1995; Bernays, E. A. *et al.*, 2004), but has been examined most extensively in caterpillars of *M. sexta* (Schoonhoven, L. M., 1969; 1978; Glendinning, J. I. *et al.*, 1999b; 2001a; 2001b; 2002). For example, 24 h of dietary exposure to a caffeine diet eliminates the aversive response to caffeine. The long-term adaptation phenomenon appears to be mediated peripherally because the dietary exposure regime profoundly desensitizes all of the bitter-sensitive taste cells to caffeine. Twenty-four hours of dietary exposure to a salicin diet also eliminates the aversive response to salicin. However, this latter adaptation phenomenon must be mediated centrally because there is no associated reduction in responsiveness of the bitter-sensitive taste cells. Taken together, these results indicate that the peripheral and central gustatory system of *M. sexta* each have independent mechanisms for overcoming the aversive response to harmless bitter compounds.

Because the long-term adaptation to salicin is mediated by the central gustatory system, and because it generalizes to related taste stimuli (Glendinning, J. I. *et al.*, 2001a; 2002), it can be viewed as a type of habituation. It is important to note, however, that the onset latency for the habituation to salicin (in *M. sexta*) is about 24 h, whereas that to sucrose (in flies and bees) is $\leq$5 min (Duerr, J. S. and Quinn, W. G., 1982; Braun, G. and Bicker, G., 1992; Scheiner, R., 2004; Scheiner, R. *et al.*, 2004). Further work is needed to determine whether these different onset latencies reflect (1) species differences, (2) greater difficulty habituating to aversive taste stimuli, and/or (3) the existence of multiple habituation mechanisms.

4.03.7.3.4 Induced food preferences

After feeding on a particular plant species for 1–2 days, many species of herbivorous insect induce a strong preference for that plant species (review in Szentesi, A. and Jermy, T., 1990). Despite the widespread occurrence of this phenomenon, the underlying physiological mechanisms are poorly understood. In all likelihood, a variety of mechanisms are activated, depending on the chemical constituents of the plant tissue and the insect species – e.g., induction of detoxification enzymes, changes in gustatory and/or olfactory responsiveness, and conditioned preferences (Bernays, E. A. and Weiss, M. R., 1996).

That taste contributes to induced food preferences was established recently in a study of *M. sexta* caterpillars, which are facultative specialists on plants in the family Solanaceae. When these caterpillars were reared on solanaceous foliage, they induced a strong and exclusive preference for the same foliage (Hanson, F. E. and Dethier, V. G., 1973; Yamamoto, R. T., 1974; de Boer, G. and Hanson, F. E., 1987; del Campo, M. L. and Renwick, J. A. A., 2000). A team of investigators discovered that indioside D (a steroidal glycoside) is one of the chemicals in the solanaceous foliage to which the caterpillars induce their preference (del Campo, M. L. *et al.*, 2001). These investigators also presented evidence that the taste cells in the caterpillar's styloconic sensilla become tuned to indioside D over the course of the induction process, and that this chemosensory tuning process is sufficient to explain the induced preference for solanaceous leaves (del Campo, M. L. *et al.*, 2001; del Campo, M. L. and Miles, C. I., 2003). According to the chemosensory tuning hypothesis, the taste cells sensitive to indioside D maintain their normal responsiveness, while those sensitive to other plant chemicals (e.g., sugars, salts, and bitter taste stimuli) become less responsive.

4.03.7.4 Health Status

A recent study demonstrated that peripheral gustatory sensitivity of two species of caterpillar changes in response to endoparasitic infection (Bernays, E. A. and Singer, M. S., 2005). More specifically, the investigators discovered that endoparasitic infections cause specific taste cells in the caterpillars to respond more vigorously to specific host plant compounds (i.e., PAs). Given that activation of the PA-sensitive taste cells stimulates increased feeding, it follows that an elevated responsiveness of the PA-sensitive taste cells would promote intake of PA-containing plant tissues. This sequence of events should benefit the caterpillars because PAs are toxic to the endoparasites and thus may help the caterpillars control (or even eliminate) the endoparasitic infection.

4.03.8 Future Directions

Despite all of the recent molecular advances in insect taste (review in Amrein, H. and Thorne, N., 2005), we still have a relatively simplistic understanding of how taste contributes to the control of feeding. This reflects a number of complicating factors. One is that

investigators have distributed their efforts over a wide range of insect species. While this approach has offered important comparative insights, it has prevented a detailed analysis of the taste system in any one species. At this point, the insect species with the best-characterized taste system include adult blowflies (*P. regina*), adult *Drosophila melanogaster*, and larval *M. sexta*. By focusing future efforts on these species, investigators will be able to build a substantial body of knowledge, and ask even more sophisticated questions.

A second factor that has limited progress on insect taste is the widespread use of long-term feeding assays to assess taste function – for example, preference tests that span 2–6 h. Given that secondary plant compounds (and nutrients) can inhibit feeding in <5 min through postoral mechanisms (Reynolds, S. E., 1990; Timmins, W. A. and Reynolds, S. E., 1992; Glendinning, J. I. and Slansky Jr., F., 1994; Glendinning, J. I., 1996), it is likely that the results from feeding tests lasting ≥2 h will reflect contributions of both oral and postoral response mechanisms. The contribution of postoral mechanisms can confound the interpretation of behavioral assays that seek to isolate taste-mediated responses. Another problem with the use of long-term feeding assays is that they weaken attempts to link neural responses of the taste system to behavior. Because electrophysiological studies usually focus on the initial milliseconds (or seconds) of response, one cannot easily extrapolate these transient neural processes to behavioral processes that span 2–6 h. A more rational approach would be to determine the operative time frame for the feeding behavior of interest, and then to examine the neural responses that occur over that time frame. For instance, given that caterpillars and flies can discriminate taste stimuli in less than 1 s (Dethier, V. G., 1968; Dethier, V. G. and Crnjar, R. M., 1982), one should focus electrophysiological analyses of discrimination on the initial 1 s of neural response. To this end, investigators could use well-established techniques for measuring immediate taste-mediated responses – for example, the proboscis extension reflex in flies and bees (Dethier, V. G., 1976) or initial biting responses in caterpillars and beetles (Dethier, V. G. and Crnjar, R. M., 1982; Frazier, J. L., 1986; Sperling, J. L. and Mitchell, B. K., 1991; Glendinning, J. I. *et al*., 2006).

A final factor that has hampered progress on insect taste is the absence of a framework for integrating taste into more generalized feeding control mechanisms. Such a framework has been developed for mammals (Spector, A. C., 2000) and has been of enormous value in helping understand how taste input modulates different aspects of the ingestive process. In mammals, taste processing has been grouped into three categories. Stimulus identification involves the discrimination of ecologically relevant taste stimuli, and the association of these taste stimuli with specific events or outcomes. These associative processes encompass both innate and conditioned responses. Ingestive motivation involves the central gustatory mechanisms that promote or inhibit the consumption of foods, and thereby represents the hedonic component of taste (i.e., whether an animal prefers or avoids a food). Digestive preparation involves the mechanisms by which taste activates feedforward mechanisms that aid in the digestive process. Application of this integrative framework to studies of insect taste would significantly enhance our ability to identify and analyze the central neuropils involved in different aspects of taste processing and better characterize phenotypic effects of genetic manipulations.

Glossary

accessory lobes (ALs) The paired deutocerebral neuropils in crustaceans that are connected to the olfactory lobes through interneurons but do not receive direct input from primary chemoreceptor neurons.

accessory olfactory bulb (AOB) The initial portion of the vertebrate central nervous system that processes information arriving from the vomeronasal organ.

aesthetasc sensilla Also called olfactory sensilla, they are the cuticular sensory structures of crustaceans that are located on the distal end of the lateral flagellum of the antennule and contain only olfactory receptor neurons that project only to the olfactory lobes.

antennal lobes The paired deutocerebral neuropils of insects that process odor information arriving from olfactory receptor neurons on the antennae; analogous to the vertebrate olfactory bulbs and the crustacean olfactory lobes.

antennules The first pair of antennae of crustaceans that are composed of basal segments at the proximal end and two flagella (lateral and medial) at the distal end.

chemoreceptor neuron (CRN) First-order neurons that detect environmental chemicals and transmit that information via their axonal projections into the central nervous system.

deutocerebrum The midbrain of arthropods (positioned between the protocerebrum and the tritocerebrum), which receives sensory information from the antenna; in crustaceans, the deutocerebrum includes the olfactory lobes, ALs, and lateral antennular neuropils.

facial lobe (FL) The primary gustatory nucleus of the medulla in teleosts that receives input from the facial taste nerve (cranial nerve VII) that innervates taste buds on the external body surface, lips, and rostral oral cavity.

lateral antennular neuropils (LANs) The paired deutocerebral neuropils of crustaceans that receive input from the CRNs and mechanoreceptor neurons that innervate the nonaesthetasc sensilla on the lateral and medial flagella of the antennules.

median antennular neuropil (MAN) The unpaired deutocerebral neuropil of crustaceans that receives input from the CRNs and mechanoreceptor neurons that innervate the nonaesthetasc sensilla of the antennules.

nonolfactory chemosensilla Also called nonaesthetasc chemosensilla, they are a diverse assortment of cuticular sensory structures located on the antennule of crustaceans, which project into the LANs and MAN.

olfactory bulb (OB) The initial portion of the central nervous system in vertebrates that processes odor information arriving from olfactory receptor neurons.

olfactory lobe (OL) In teleosts, the portion of the forebrain that receives input from the olfactory tract, the axons of mitral cells, the output neurons of the OB. In crustaceans, the deutocerebral neuropil that receives input from the axons of olfactory receptor neurons of the aesthetasc sensilla of the lateral flagellum of the antennule.

olfactory receptor (OR) Molecules, typically G-protein-coupled receptors, located on CRNs, to

which odorant molecules bind to initiate the olfactory transduction process.

olfactory receptor neuron (ORN) Primary receptor neurons whose dendrites contain the molecular ORs and whose axons project via the olfactory nerve into the olfactory region of the brain; in fish, the olfactory nerve is cranial nerve I projecting to the OB, and in crustaceans, it is a tract of the antennular nerve projecting to the OL.

perireception Events occurring around the olfactory and taste receptors that influence the chemical environment and the reception of chemical stimuli.

vagal lobe (VL) The primary gustatory nucleus of the medulla in teleosts that receives input from taste activity transmitted by the vagal taste nerve (cranial nerve X) that innervates taste buds within the oral cavity caudal to the first gill arch.

4.04.1 Introduction

The aim of this chapter is to provide a basic understanding of the chemosensory structures and mechanisms found in aquatic animals. Because of the vast literature on such an enormous topic, we have had to narrow considerably the scope of our review. First, we focus only on the major aquatic animal models in the study of chemoreception. We have selected two groups, representing the vertebrates and the invertebrates: the teleosts (bony fishes) and decapod crustaceans (spiny lobsters, clawed lobsters, crayfish, and crabs). Second, we focus on topics more aligned with biomedical than ecological issues: general structure of the chemosensory cells and their organization, and mechanisms of chemosensory transduction and the neural processing of chemical stimuli. Due to space limitations, topics such as pheromones (Stacey, N. E. and Sorensen, P. W., 2002; 2005) and the chemosensory basis of homing behavior (Døving, K. B., 1996; Døving, K. B. and Stabell, O. B., 2003) in fishes are not discussed. This chapter is also not an encyclopedic listing of how chemicals may influence various behaviors of aquatic organisms but focuses on chemosensory behaviors where there is better understanding of the neurophysiological substrate. Due to the necessary selection of research reports to include in this chapter from the numerous research articles that have allowed the field of aquatic chemoreception to progress to date, we take this opportunity to apologize to our coworkers whose work was not given the treatment that it deserves. Previously published excellent reviews in this field include Kleerekoper H. (1969), Hara T. J. (1982; 1992), Atema J. *et al.* (1989), Carr W. E. S. *et al.* (1990), Sandeman D. C. *et al.* (1992), Derby C. D. (2000), Weissburg M. J. (2000), Zimmer R. K. and Butman C. A. (2000), McClintock T. S. and Xu F. (2001), Ache B. W. (2002), Schachtner J. *et al.* (2005), Ache B. W. and Young J. M. (2005), Moore P. A. and Berman D. A. (2005), and Atema J. and Steinbach M. A. (2007).

For terrestrial animals including mammals and insects, olfaction and taste are neatly distinguished based on the physical medium in which they operate. Olfaction is for volatile molecules that are delivered in air to the receptor epithelium, and taste is for water-soluble molecules that are delivered in an aqueous medium to the receptors. For fish and most crustaceans, which live in aquatic environments and whose chemosensory world is limited to water-soluble rather than to volatile chemical stimuli, this distinction between olfaction and taste is nonsensical.

Olfaction and taste are also distinguished within the vertebrates based on anatomical organization, regardless of the media in which the animals live. Olfaction is mediated by the olfactory nerve (cranial nerve (CN) I), and taste is mediated by modified epithelial (taste) cells innervated by CN VII (facial), IX (glossopharyngeal), or X (vagal), regardless of whether the animal is a human living in air, a fish living in water, or a frog that lives in both worlds. Yet this anatomical distinction, which works for vertebrates, is not instructive for the other ~97% of the animals – that is, the invertebrates.

A third way of distinguishing olfaction and taste is a functional one. Taste mediates more simple, reflexive behaviors – grabbing, biting, and swallowing (i.e., consummatory behavior), whereas olfaction mediates more complex behaviors, that is, search for chemicals from a distance, courtship behavior, and learning about odors (Atema, J. 1977; 1995); however, taste in some fish like catfishes mediates searching for distant food (i.e., appetitive behavior).

Another way to identify olfaction, at least for vertebrates and arthropods, is the organization of the first-order processing regions in the brains that receive the

peripheral chemosensory input. This region – the olfactory bulb (OB) of vertebrates, the antennal lobe of insects, and the olfactory lobe of crustaceans – is organized into glomeruli, which contain the synapses between the olfactory receptor neurons (ORNs) and second-order neurons. Furthermore, there is an odotopic organization to these glomeruli, in which odorants of different chemical categories generate distinctive activation patterns across the glomeruli.

In this chapter, olfaction and taste in fish is distinguished according to the vertebrate-specific pattern of nerve innervation, which is consistent with the olfaction-has-glomeruli model. For crustaceans, the glomerular definition of olfaction, and thus their olfactory pathway, is defined as the aesthetasc–olfactory lobe pathway (as described below). However, distinguishing between olfaction and taste creates a binary categorization that does not adequately describe the diversity of chemical senses of any animal, including fish and crustaceans. For example, this categorization applied to fish combines the oropharyngeal pathway and the extraoral pathway, even though they differ in cranial innervation (IX/X versus VII) and function – the former controlling reflexive swallowing (consummatory behavior) and the latter for locating distant food and taking it into the mouth (appetitive behavior). In addition, this categorization does not include the solitary chemoreceptor cells, which individually are anatomically similar to taste cells, but they are not organized into bud-like structures and they synapse with taste, trigeminal, or spinal nerves (Kapoor, B. G. and Finger, T. E., 2003). For crustaceans, this binary classification results in identifying all nonaesthetasc chemoreceptive neurons (CRNs) as taste, even though they are extremely diverse in how they are packaged into functional units, how they connect to the central nervous system (CNS), their organization within the CNS, and the behaviors they mediate (see below). Combining them into a single taste category is too simplistic and restrictive, and thus, in this chapter they are termed nonaesthetasc or nonolfactory chemosensors.

4.04.2 Olfactory Transduction

4.04.2.1 Introduction

ORNs of teleosts and crustaceans have served as important models not only for understanding the specifics of transduction in these species but also for elucidating fundamental and general principles of olfactory transduction (Ache, B. W. and Zhainazarov, A. B., 1995; Bruch, R. C., 1996; Ache, B. W. 2002; Ache, B. W. and Young, J. M. 2005). Transduction processes that are well characterized and that we describe in this section include perireception (in crustaceans), molecular biology of receptor molecules (in fish), second messengers, ion channels, and kinases. Much has been learned about chemoreception in fishes from only a few animal models of the more than 25 000 extant teleost species. These model species include catfishes, zebrafish, goldfish, and salmonids. For crustaceans, the spiny lobster *Panulirus argus* and the clawed lobster *Homarus americanus* are the models of choice for studying olfactory transduction.

4.04.2.2 Fish

Genes for putative olfactory receptors (ORs) are identified from several teleosts (Ngai, J. *et al.*, 1993; Byrd, C. A. *et al.*, 1996; Cao, Y. *et al.*, 1998; Sun, H. *et al.*, 1999; Kondo, R. *et al.*, 2002). These ORs are G-protein-coupled receptors, although they are structurally highly dissimilar from the ORs of mammals and other vertebrates.

OR activation by odorants results in the formation of second messengers – cAMP and/or inositol 1,4,5-trisphosphate (IP_3)/diacylglycerol (DAG). These second messengers lead to the depolarization of ORNs via the gating of (1) cyclic nucleotide-gated (CNG) channels and subsequently Ca^{2+}-activated Cl^- channels (for the cAMP pathway), which amplifies the odor-activated signal (Schild, D. and Restrepo, D., 1998), (2) ciliary IP_3 channels (Bruch, R. C., 1996; Schild, D. and Restrepo, D., 1998), or (3) TRPC2 (transient receptor potential) channels (Sato, Y. *et al.*, 2005), leading in all three cases to increasing intracellular Ca^{2+}. Although excitatory conductances have only been described to date, ORNs of teleosts also exhibit odorant-induced suppression (Kang, J. and Caprio, J., 1995b), but little definitive information is known in fish about the responsible mechanisms. The cAMP pathway is the generally accepted excitatory mechanism for the ciliated ORNs (cORNs) of tetrapods, especially mammals (Gold, G. H., 1999), although recent evidence suggests that odor transduction in mammals likely also involves a cAMP-independent pathway (Lin, W. *et al.*, 2004). However, in microvillous receptor neurons of the vomeronasal system, a DAG transduction pathway was recently implicated (Lucas, P. *et al.*, 2003). Fish, however, do not possess a vomeronasal

system, and both cORNs and microvillous ORNs (mORNs) are present in the main olfactory epithelium. Recent evidence from teleosts suggests that specific odorants activate ORs and the cAMP second messenger system in cORNs (Sato, K. and Suzuki, N., 2000; Hansen, A. *et al*., 2003; Schmachtenberg, O. and Bacigalupo, J., 2004; Sato, Y. *et al*., 2005), whereas other odorants activate members of the V2R gene family and the IP_3 (and possibly the diacyl glycerol) pathway of mORNs (Speca, D. J. *et al*., 1999; Hansen, A. *et al*., 2003; Sato, Y. *et al*., 2005).

A recent molecular modeling study identified key amino acid residues that are involved in ligand binding and selectivity for the L-arginine OR (a V2R olfactory receptor) in goldfish (Luu, P. *et al*., 2004). Identified was a key residue, methionine 389, in goldfish OR 5.24 that provides OR selectivity to basic amino acids, and another residue, lysine 386, in zebrafish that is critical for OR selectivity to acidic amino acids. Although neither the odorant nor receptor types are known for crypt ORNs, the transduction mechanism in channel catfish likely utilizes $G\alpha_o$ (Hansen, A. *et al*., 2003), whereas in goldfish the same crypt ORN expresses both $G\alpha_o$ and $G\alpha_q$ (Hansen, A. *et al*., 2004).

4.04.2.3 Crustaceans

The importance of perireceptor events, which influence the odorant environment around the receptors, has been well studied in spiny lobsters. Flicking of the olfactory organ leads to periodic loading and unloading of chemical stimuli around the densely packed aesthetascs (Schmitt, B. C. and Ache, B. W., 1979; Koehl, M. A. R. *et al*., 2001). Lobsters, fish, and other aquatic animals do not appear to have odorant-binding proteins, whose function in terrestrial animals may include delivery of odorants to receptors or even be more directly central to receptor activation (Vogt, R. G., 2005; Xu, P. *et al*., 2005). Lobsters, however, do have several perireceptor elements that are involved in inactivating or removing odorants from the receptor environment. These include ectoenzymes, such as ectonucleotidases, to convert the excitatory compounds AMP and ATP into non-excitatory adenosine, and transporters for odorants such as taurine, adenosine, and glutamate (Carr, W. E. S. *et al*., 1990).

Despite the fact that genes for ORs are not yet identified in any crustacean, other lines of inquiry, including biochemical, molecular, and physiological, reveal much about the nature of these receptors and their role in transduction. Patch clamp (Hatt, H. and Ache, B. W., 1994), binding studies (Olson, K. S. *et al*., 1992), and transmission electron microscopy (Blaustein, D. N. *et al*., 1993) demonstrate odorant-binding receptors on the dendritic membrane of ORNs. Furthermore, biochemical analysis of receptor–ligand binding shows that high (nM to pM) and low (μM) affinity sites for taurine, AMP, glutamate, and arginine receptors on the ORN dendrites (Olson, K. S. *et al*., 1992; Michel, W. C. *et al*., 1993; Olson, K. S. and Derby, C. D., 1995).

These receptors are G-protein-coupled receptors, as demonstrated by physiological, biochemical, and molecular studies. Odor-activated physiological responses of ORNs are affected in predictable ways by blockers or activators of G proteins (Fadool, D. A. *et al*., 1995). In addition, several G-protein subunits ($G\alpha_i$, $G\alpha_s$, $G\alpha_q$, and $G\beta$), phospholipase C-β (PLC-β), and a G-protein-coupled receptor kinase are identified from cDNA libraries of the antennules of lobsters (*Homarus*) (McClintock, T. S. and Xu, F., 2001). Furthermore, functional assays demonstrate a role for these molecules in either activation or desensitization of odorant responses (McClintock, T. S. and Xu, F., 2001).

Lobster ORNs have two distinct G-protein-coupled second messenger pathways (Ache, B. W., 2002). One of these is excitatory, mediated by phosphoinositol signaling. In this pathway, $InsP_3$ activates a cation-selective channel, leading to an inward conductance that normally depolarizes the cell. The other G-protein pathway is inhibitory, mediated by cyclic nucleotide signaling. In this pathway, cAMP activates an outward conductance, carried by K^+ through a CNG K^+ channel (Michel, W. C. and Ache, B. W., 1992), and suppresses a steady-state Cl^- channel (Doolin, R. E. *et al*., 2001; Doolin, R. E. and Ache, B. W., 2005a). Both excitatory and inhibitory pathways are present in the same ORN, as revealed by electrophysiological recordings from both individual cells (McClintock, T. S. and Ache, B. W., 1989; Michel, W. C. *et al*., 1991) and from patches of ORN dendritic membranes (Hatt, H. and Ache, B. W., 1994).

A given odorant can be excitatory to some ORNs and inhibitory to others (Michel, W. C. *et al*., 1991) and can activate either the inward or the outward conductance (Doolin, R. E. and Ache, B. W., 2005b). Furthermore, it appears that the two inhibitory conductances, Cl^- and K^+, are not odor specific (Doolin, R. E. and Ache, B. W., 2005b). Thus, no odorant is exclusively excitatory or inhibitory across cells, and

no receptor exclusively mediates excitation or inhibition.

These two second messenger-mediated pathways are the first step in odor activation, and this is followed by a second step that amplifies this signal and sets the gain of the ORN (Ache, B. W., 2002). This amplification involves a nonselective cation channel, which is a member of the TRP channel family (Zhainazarov, A. B. *et al.*, 2001; Bobkov, Y. V. and Ache, B. W., 2005) and may be functionally similar to the Ca^{2+}-activated Cl^- channel that participates in odor detection in mammals (Kleene, S. J., 1997).

These and other results lead to the conclusion that individual ORNs of spiny lobsters contain a rich diversity of transduction molecules. Together, these diverse intracellular pathways allow ORNs to do substantial processing and integration (Ache, B. W. *et al.*, 1998). In addition, ORN responsiveness can be modulated by gamma-aminobutyric acid ($GABA_A$) receptors on the soma (Zhainazarov, A. B., *et al.*, 1999) and by centrifugal synaptic inhibition at their axonal terminals (Wachowiak, M. *et al.*, 2002). An important question is, whether having ORNs with such complex integration properties is a feature of simpler animals (i.e., invertebrates), which have fewer ORNs than vertebrates, or whether vertebrate ORNs are similarly complex. Although this topic is hotly debated, recent evidence indicates that mammalian ORNs have both cAMP and IP_3 pathways that can interact in complex ways (Spehr, M. *et al.*, 2002; Zhainazarov, A. B. *et al.*, 2004).

4.04.2.4 Overview

Olfactory transduction in teleosts and crustaceans has many commonalities with each other and with other characterized ORNs. ORs are G-protein-coupled receptors linked via second messenger pathways to ion channels. A diversity of olfactory transduction cascades that lead to the activation of CNG, IP_3, and/or TRPC2 channels exist. Other channels are secondarily activated, which in turn amplify the signal. Single ORNs of teleosts and lobsters can have more than one second messenger pathway. In lobsters, these include specific excitatory and inhibitory pathways. For teleosts, dual excitatory ORN pathways are identified, but it is currently unknown whether odorant-induced suppression requires an additional inhibitory transduction pathway, or whether specific odorants can affect the resident pathways to result in suppression (Hallem, E. A. *et al.*, 2004). Multiple transduction cascades in individual cells can enhance the diversity of odor responses generated by ORNs. Perireceptor events are important to aquatic animals – for example, ectoenzymes and transporters clean up the odor environment around the ORs – but other perireceptor processes not relevant to aquatic animals are absent – for example, no odorant-binding proteins.

4.04.3 Properties of the Peripheral Chemical Detectors

4.04.3.1 Introduction

Peripheral chemosensory systems have the task of extracting biologically important information about the type, amount, and temporal dynamics of environmental chemicals and sending this information to the CNS. In this section, we review the organization of peripheral olfactory systems of fish and crustaceans and describe how they perform these important tasks.

4.04.3.2 Fish

4.04.3.2.1 Specificity of single olfactory receptor neurons

Although numerous studies in fishes tested amino acids as odorant stimuli, few investigations focused primarily on the odorant specificities of individual ORNs (Mac Leod, N. K., 1976; Meredith, M. and Moulton, D. G., 1978; Meredith, M., 1981; Restrepo, D. *et al.*, 1990; Ivanova, T. T. and Caprio, J., 1993; Kang, J. and Caprio, J., 1995a; 1995b; 1997; Sato, K. and Suzuki, N., 2001; Friedrich, R. W. and Laurent, G., 2004). Electrophysiological studies in the channel catfish indicated that single ORNs had ongoing spontaneous activity ($\sim$5 spikes s^{-1}) that could be elevated or suppressed in response to amino acids (Kang, J. and Caprio, J., 1995b; 1997); furthermore, response suppression (25%) was the dominant response type (13% excited; 62% nonresponsive). A few single ORNs showed excitation to some amino acids and suppression to others. In an innovative study to reveal odor-induced spike activity of single ORNs whose responses were likely to have been shunted from an extracellular recording electrode due to the high ionic content of the pond water bathing the olfactory organ, the olfactory organ of bullhead catfish was bathed in water of low ionic content (Valentinčič, T. *et al.*, 2005). ORNs having low or no spontaneous activity were excited by specific amino acids. That excitation is the major type of

response to amino acids in teleost ORNs was also reported for zebrafish where only 4% (3 of 76 ORNs) were suppressed by an amino acid (Friedrich, R. W. and Laurent, G., 2004). None of these reports provided evidence for the existence of specific neuron types that were excited by particular amino acids.

Current unpublished data (Nikonov A. A. and Caprio J.), however, indicate the existence of ORNs that are highly specific to basic and neutral amino acids, respectively, similar to those reported for group I neurons in the OB (see section 4.04.4.2.4) and FB (see Nikonov, A. A. and Caprio, J., 2007).

4.04.3.2.2 Correlation between olfactory receptor neuron type, transduction process, and odorant sensitivity

Several morphological types of ORNs occur in the olfactory epithelium of teleosts: ciliated (c), microvillous (m), and crypt (cp) (Figure 1). However, controversy exists as to whether these different cell types process specific types of odorants (see Eisthen, H. L., 2004, for a review). A whole-cell patch clamp study of isolated ORNs from rainbow trout indicated, however, that mORNs responded specifically to amino acids, whereas cORNs were more broadly tuned, responding to a wide variety of odorants including amino acids (Sato, K. and Suzuki, N., 2001). That mORNs also respond to amino acids was indicated via activity-dependent labeling by the ion channel permeant probe, agmatine, in zebrafish (Lipschitz, D. L. and Michel, W. C., 2002). Additional evidence to suggest that mORNs respond to amino acids was obtained in the goldfish where a V2R receptor for L-arginine was shown to couple to PLC and IP_3 production and be expressed in ORNs whose cell bodies were located superficially in the olfactory epithelium, a characteristic of mORNs (Speca, D. J. *et al.*, 1999). Evidence that cORNs also respond to amino acids, as reported above for rainbow trout, comes from a perforated patch study of isolated cORNs in a marine fish, the Cabinza grunt (*Isacia conceptionis*). cORNs in this marine species responded to amino acids through the activation of CNG channels and calcium-activated conductances (Schmachtenberg, O. and Bacigalupo, J., 2004), confirming a similar report for cORNs in rainbow trout (Sato, K. and Suzuki, N., 2000).

The recent determination of the odotopic organization within the OB of a few species of teleosts also provided the pathway to link odorant type with receptor cell morphology. By placing DiI, a postmortem retrograde tracer, into select and discrete regions of the teleost OB shown to be excited by specific classes of odorants, a direct link between ORN morphology and the type of odorant detected was recently derived from studies in crucian carp, channel catfish, and goldfish. For crucian carp, the evidence suggests that mORNs respond to food odors (Hamdani, E. H. *et al.*, 2001a), whereas cORNs are involved in the detection of alarm substances (Hamdani, E. H. and Døving, K. B., 2002). For channel catfish, the combination of a variety of experimental procedures (light and electron microscopy, *in situ* hybridization, immunocytochemistry, electrophysiology, and pharmacology) provided the necessary information to link the specific anatomical type of ORN with the type of molecular OR, its specificity for odorant type, and its probable mechanism of transduction (Hansen, A. *et al.*, 2003). In channel catfish, bile salt odorants (possible socially relevant cues in teleosts; Sorensen, P. W. and Caprio, J., 1998), are detected primarily by ORs expressed within cORNs and transduced via the $G\alpha_{olf}$/cAMP cascade, whereas nucleotides are detected by V2Rs expressed in mORNs but transduced via an unknown (neither $G\alpha_{olf}$/cAMP nor $G\alpha_{q/11}$/PLC) cascade; however, recent evidence in zebrafish suggests that nucleotides possibly activate TRPC2 channels expressed in mORNs (Sato, Y. *et al.*, 2005). Amino acid odorants in channel catfish activate both cORNs (expressing ORs) and mORNs (expressing V2Rs) but via different transduction pathways in the two types of ORNs (Hansen, A. *et al.*, 2003). For goldfish, cORNs also express ORs and $G\alpha_{olf}$, and mORNs express V2R genes but are primarily immunoreactive for $G\alpha_o$; however, $G\alpha_{i-3}$ and $G\alpha_q$ are also indicated for mORNs that are shorter and that possess more stiff microvilli than other mORNs (Hansen, A. *et al.*, 2004). Independent pharmacological evidence in goldfish also indicated that bile salt odorants and some amino acids are detected via the cAMP pathway and that amino acids also utilize the IP_3 transduction pathway (Rolen, S. H. *et al.*, 2003), which is consistent with previous molecular investigations (Bruch, R. C., 1996).

Sex pheromones in teleosts are gonadal steroids and prostoglandins (Sorensen, P. W. and Caprio, J., 1998). Recent evidence in crucian carp indicate that axons of cp neurons project to the ventral OB where they synapse with mitral cells whose axons form the lateral bundle of the medial olfactory tract and mediate sexual behavior (Hamdani, E. H. and Døving, K. B., 2006; Lastein, S. *et al.*, 2006; Weltzien, F. *et al.*, 2003).

4.04.3.3 Crustaceans

4.04.3.3.1 Organization

Being arthropods, crustaceans have an exoskeletal covering. Consequently, their chemosensory neurons are packaged into thin extensions of the cuticle, called setae or sensilla. A rich diversity of sensilla exists, which can be classified into olfactory and nonolfactory chemosensilla.

4.04.3.3.1.(i) Olfactory sensilla The olfactory sensilla, called aesthetascs, have been recognized in many crustacean taxa (Grünert, U. and Ache, B. W., 1988; Hallberg, E. *et al.*, 1992). Aesthetascs are distinguished by their peripheral structure and central connections. They are the only sensilla known to be innervated solely by chemosensory neurons and are typically richly innervated (hundreds of ORNs in some species such as spiny lobsters) (Derby, C. D. *et al.*, 2003). Aesthetascs are located on the paired first antennae (antennules) but only on the distal end of the lateral flagellum of the antennule (Figure 2). Chemical stimuli pass through the porous cuticle of the aesthetascs and bind to receptor sites on the ORN dendrites. Each mature aesthetasc contains representatives of each of the functional types of ORNs, and thus, aesthetascs appear to be functional units of olfaction (Steullet, P. *et al.*, 2000b). The axons of the aesthetasc ORNs project ipsilaterally to the olfactory lobes (Schmidt, M. and Ache, B. W., 1996b) (see Section 4.04.4). Although aesthetascs are present in many crustacean taxa, they differ in their structure in functionally significant ways. For example, the organization of aesthetascs differs in aquatic, semiterrestrial, and terrestrial species (Ghiradella, H. *et al.*, 1968; Stensmyr, M. C. *et al.*, 2005). Aesthetasc sensilla contain not only sensory neurons but also supporting cells, which have functional overlap with supporting cells in insect and vertebrate olfactory organs. For example, supporting cells include (1) secretory cells associated with glands that produce a substance that likely coats the external surface of the aesthetasc cuticle (Schmidt, M. and Derby, C. D., 2005); (2) cells that secrete the sensillar cuticle; and (3) cells that produce ectoenzymes and

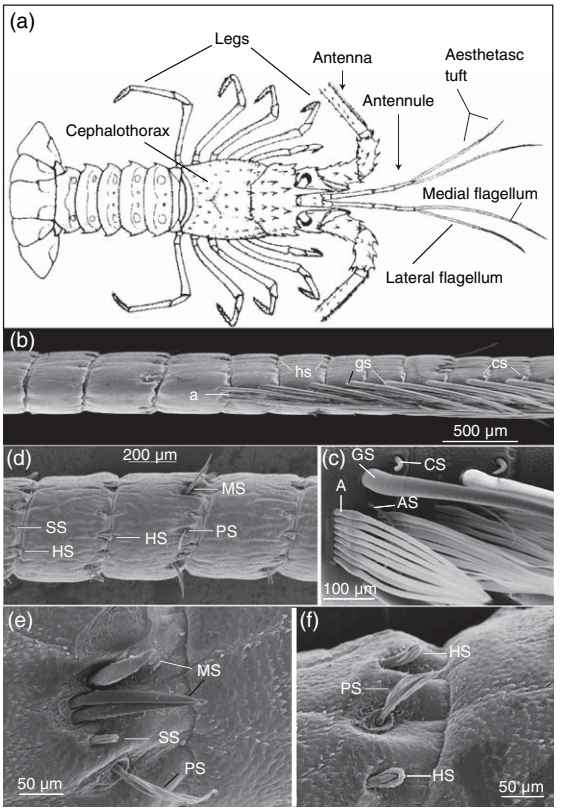

Figure 2 Peripheral chemosensory structures in spiny lobsters. (a) Drawing of a spiny lobster, *Panulirus argus*, showing the chemosensory organs. Each of the antennules (first antennae) has a medial flagellum and lateral flagellum. The sensory neurons are packaged into sensilla. The aesthetasc tuft, which contains aesthetasc sensilla and other associated sensilla (shown in the right half of b and in c), is located on the ventral side of the distal half of the lateral flagellum. Chemoreceptor neurons that innervate sensilla other than aesthetascs are called nonaesthetasc or nonolfactory chemoreceptor neurons. (b–f) Scanning electron micrographs of antennular sensilla. (b) The lateral flagellum at the boundary of the aesthetasc tuft. The aesthetasc tuft is to the right in this figure. The flagellum is divided into annuli, 12 of which are shown here. Each annulus in the aesthetasc region bears a similar complement of sensilla (shown in c), and each annulus in the nonaesthetasc region bears a similar complement of setae (shown in d–f). (c) Tuft region of the lateral flagellum. (d) Nontuft region of the lateral flagellum; the medial flagellum has similar types and organization of sensilla to this region. (e, f) High magnification views of nonaesthetasc regions of the lateral flagellum, showing four types of nonaesthetasc sensilla. A, aesthetasc sensillum; AS, asymmetric sensillum; CS, companion sensillum; GS, guard sensillum; HS, hooded sensillum; MS, medium-length simple sensillum; PS, plumose sensillum; SS, setuled sensillum. From figure 1 of Steullet, P., Dudar, O., Flavus, T., Zhou, M., and Derby, C. D. 2001. Selective ablation of antennular sensilla on the Caribbean spiny lobster *Panulirus argus* suggests that dual antennular chemosensory pathways mediate odorant activation of searching and localization of food. J. Exp. Biol. 204, 4259–4269, used with permission.

transporters that regulate the chemical environment of the fluid bathing the sensory cells (Carr, W. E. S. *et al.*, 1990; Gleeson, R. A. *et al.*, 1992).

4.04.3.3.1.(ii) Nonolfactory chemosensilla Nonolfactory sensilla are on all appendages and most of the body surface. Some of these, such as those on the mouthparts, are clearly gustatory in function, in that they control the ingestion of food (Derby, C. D. and Atema, J., 1982; Garm, A. *et al.*, 2005). Others are found on the legs, antennules, antennae, and general body surface (Derby, C. D., 1982; Schmidt, M. and Gnatzy, W., 1984; Cate, H. S. and Derby, C. D., 2001; 2002; Schmidt, M. and Derby, C. D., 2005), and consequently, these have many different functions. The nonolfactory chemosensilla are morphologically diverse, but they do have several common features. They are at least bimodally innervated, containing not only chemosensory neurons but also mechanosensory neurons (Schmidt, M. and Gnatzy, W., 1984; Cate, H. S. and Derby, C. D., 2002; Garm, A. *et al.*, 2005). Nonolfactory sensilla are more sparsely innervated than aesthetascs, typically with two or three mechanoreceptor neurons and fewer than 20 CRNs. Their cuticle is thick and not porous, and thus, chemicals enter through a terminal pore. The chemosensory neurons of these sensilla do not project to the olfactory lobe but rather to other neuropils in the CNS. This occurs even for nonolfactory antennular chemosensory neurons, which project ipsilaterally to the lateral antennular neuropils (LANs) and to the median antennular neuropil (MAN) (Schmidt, M. and Ache, B. W., 1996a) (see Section 4.04.4).

4.04.3.3.2 Sensitivity

4.04.3.3.2.(i) Response thresholds Olfactory and nonolfactory receptor neurons often differ in sensitivity. For *P. argus*, the sensitivity of antennular CRNs is much greater than for mouthpart CRNs (Thompson, H. A. and Ache, B. W., 1980; Derby, C. D. *et al.*, 1991; Garm, A. *et al.*, 2005). For example, thresholds for antennular CRNs (which include aesthetasc ORNs) are typically nanomolar and sometimes lower, whereas mouthpart CRNs have micromolar thresholds.

4.04.3.3.2.(ii) Tuning Crustaceans are sensitive to chemicals associated with most biologically important items, including food stimuli, social and sexual pheromones, settlement factors, and defensive compounds (Atema, J., 1988; Carr, W. E. S., 1988; Zimmer, R. K. and Butman, C. A., 2000; Kicklighter, C. E. *et al.*, 2005). Differences in sensitivity among species are partly

attributable to the habitat in which they live. For example, for aquatic crustaceans, all sensors, including olfactory, are stimulated by water-soluble compounds. For terrestrial crustaceans, the antennules are sensitive to volatile chemicals, whereas the legs and mouthparts are sensitive to water-soluble stimuli (Rittschof, D. and Sutherland, J. P., 1986; Wellins, C. A. *et al.*, 1989; Stensmyr, M. C. *et al.*, 2005). Trophic level also accounts for interspecific differences in sensitivity. For example, carnivores such as *Panulirus* and *Homarus* have CRNs that respond to small, nitrogen-containing compounds – amino acids, amines, nucleotides, and peptides – that are prevalent in tissues of their animal prey and are relatively insensitive to carbohydrates and sugars (Zimmer-Faust, R. K. and Case, J. F., 1982a; Carr, W. E. S., 1988; Derby, C. D. and Atema, J., 1988; Zimmer-Faust, R. K., 1993). Herbivores and omnivores, such as fiddler crabs (Weissburg, M. J. and Zimmer-Faust, R. K., 1991), ghost crabs (Robertson, J. R. *et al.*, 1981; Trott, T. J. and Robertson, J. R., 1984), kelp crabs (Zimmer-Faust, R. K. and Case, J. F., 1982b), and crayfish (Ashby, E. A. and Larimer, J. L., 1965), often are sensitive to sugars common to plants, bacteria, and diatoms, as well as to some amino acids.

4.04.3.3.2.(iii) Specificity The CRNs of crustaceans tend to be narrowly tuned, responding with high specificity to one compound or a set of structurally related compounds. Examples include CRNs of *H.americanus* tuned to predominantly to taurine, hydroxy-L-proline, or L-glutamate (Voigt, R. and Atema, J., 1992), and antennular CRNs of *P.argus* tuned primarily to taurine, glutamate, AMP, ATP, or ammonium (Derby, C. D. *et al.*, 1991; Derby, C. D., 2000). In the crayfish *Austropotamobius torrentium*, leg CRNs are less narrowly tuned but still have specificity to one of the following classes of compounds – amino acids, pyrimidines, or amines (Bauer, U. and Hatt, H., 1980; Bauer, U. *et al.*, 1981).

Within a species, there may be differences in specificity of CRNs in different organs. For example, in *P. argus*, individual antennular CRNs have narrower response profiles than mouthpart chemoreceptors (Garm, A. *et al.*, 2005).

Physiological studies of CRNs suggest that there are as many as a dozen types of molecular receptors that are heterogeneously distributed across the CRNs. Do single cells express a single receptor type, or more than one? It is often stated that ORNs of mammals and *Drosophila* express only one type of receptor, but this idea is being questioned in the face of new data (Mombaerts, P., 2004; Goldman, A. L. *et al.*, 2005), and it certainly is not true for CRNs in other animals such as *C. elegans* (Troemel, E. R., 1999). Although genes for chemoreceptors have not been identified in any crustacean, physiological studies strongly suggest that a given cell type has multiple receptor types, each coupled to either an excitatory or an inhibitory transduction cascade (see Section 4.04.2). However, the density of the receptor types on a CRN may vary, thus creating high response specificity (Cromarty, S. and Derby, C., 1997).

4.04.3.3.3 Temporal properties

Chemical stimuli in nature, even those released at a constant rate from a single odor source, are patchy and discontinuous. This is due to turbulence, which is ever-present though at different degrees in different environments. The temporal features of chemical stimuli influence the response pattern of a cell and consequently an animal's ability to find an odor source (Atema, J., 1995; Weissburg, M. J., 2000; Zimmer, R. K. and Butman, C. A., 2000; Koehl, M. A. R. *et al.*, 2001). Since the ability of CRNs to resolve temporal fluctuations determines the animal's ability to respond to them, it is important to identify these properties. The frequency following of CRNs is dependent on adaptation and disadaptation rates (Atema, J., 1995). Many crustacean CRNs have phasotonic response profiles, although this varies across cells (Borroni, P. F. and Atema, J., 1988; 1989; Weissburg, M. J. and Derby, C. D., 1995; Garm, A. *et al.*, 2005). CRNs on *Homarus* antennules can follow 4–5 odor pulses per second (Gomez, G. and Atema, J., 1996a; 1996b; Gomez, G. *et al.*, 1999). Since temporal variability of this magnitude is common in aquatic environments (see the above references), this ability to follow such pulses is obviously adaptive.

4.04.3.4 Processing Chemical Information by Single Peripheral Chemoreceptor Neurons of Crustaceans

To summarize our knowledge of neural coding by crustacean peripheral CRNs using a parallel construction with the section Processing Taste Information by Single Peripheral Taste Fibers by single peripheral taste fibers, we offer the following points:

1. Information about different classes of chemical stimuli can be transmitted to the CNS by different groups or types of CRNs; for example, the antennules, legs, and mouthparts of spiny lobsters and American lobsters have some CRNs most sensitive

to one or several amino acids, others most sensitive to one or several adenine nucleotides, and others most sensitive to ammonium ions (Voigt, R. and Atema, J., 1992; Derby, C. D., 2000; Garm, A. *et al.*, 2005).

2. The specificity of single CRNs is not limited to a particular class of chemical stimuli, although the strongest stimulus is usually several orders of magnitude more stimulatory than other stimuli; for example, taurine-best cells on antennules of spiny lobsters may also be sensitive to other amino acids, AMP, and ammonium, although the thresholds for taurine are 100–10 000 lower than for the other stimuli (Cromarty, S. and Derby, C., 1997).
3. Different CRNs having widely different tuning to members of the same class of chemicals can exist within the sensory appendage; for example, populations of CRNs with different amino acid specificities occur on the antennules, legs, and mouthparts of lobsters (Derby, C. D. *et al.*, 1991; Voigt, R. and Atema, J., 1992; Derby, C. D., 2000).
4. CRNs in different sensory appendages within the same species can have different chemical specificities; for example, in the American lobster, CRNs highly sensitive to hydroxy-L-proline are more abundant on the antennule than the legs or mouthparts (Voigt, R. and Atema, J., 1992).
5. The proportion and types of CRNs in different sensory appendages can vary within the same species. For example, cells with best responses to either hydroxy-L-proline, taurine, L-arginine, L-glutamate, betaine, and ammonium chloride occur in the antennules, legs, and mouthparts of the American lobster but in different proportions (Voigt, R. and Atema, J., 1992).
6. L-Amino acids are much more stimulatory than their respective D-isomers, but receptors for some D-isomers do exist (Michel, W. C. *et al.*, 1993).
7. Stimulus quantity appears to be coded by the frequency of action potentials generated. For individual CRNs, some have a dynamic concentration–response range of 5–6 log units of stimulus concentration, while others have more truncated concentration–response relationships. The absolute concentrations to which cells are responsive can differ widely (Derby, C. D. and Atema, J., 1988; Borroni, P. F. and Atema, J., 1988; 1989; Derby, C. D. *et al.*, 1991; Cromarty, S. and Derby, C., 1997).
8. Except for one report (Hatt, H., 1986), CRNs are not known to be sensitive to mechanical stimulation. However, they can respond to temperature and salinity changes (Schmidt, M., 1989).

4.04.3.5 Overview

Fish and crustaceans have a diversity of peripheral chemoreceptors. In teleosts, three types of ORNs have been identified: ciliated, microvillous, and crypt, which differ in their mode of transduction. The crustacean olfactory organ has many types of chemosensory neurons packaged into units called sensilla, but one of these sensillar types – the aesthetascs – is an olfactory sensillum based on its organization and central projections. The ability of fish and crustacean ORNs to detect and identify the type, amount, and temporal dynamics of chemical stimuli is well understood. ORNs generally have low spontaneous spiking activity, which is more usually increased but sometimes decreased by chemical stimulation. The population of ORNs on an olfactory organ responds to many chemicals, with small nitrogenous compounds, such as amino acids, amines, and nucleotides being the most effective. However, individual ORNs differ in their response specificities, which can be quite narrow. The response of ORNs increases in a concentration-dependent manner. Crustacean ORNs can follow pulses of chemicals up to at least 4–5 per second.

4.04.4 Organization of Central Olfactory Pathways

4.04.4.1 Introduction

The organization of the olfactory pathway of fishes and crustaceans has many elements common with that of other vertebrates, arthropods, and even other taxa. This section examines the connectivity between the olfactory periphery and CNS, the organization of the olfactory CNS, and how odor responses from the periphery are shaped by synaptic interactions within the olfactory CNS.

4.04.4.2 Fish

4.04.4.2.1 Organization of the olfactory bulb

Although the general anatomical organization of the olfactory system is similar across the vertebrates, the structure of the neural connections within the OB can be different between fish and mammals (reviewed in Dryer, L. and Graziadei, P. P. C., 1994). In contrast to mammals where a single mitral cell generally projects a single primary dendrite to a single large (50–200 μm in diameter), well-defined

glomerulus, mitral cells in the fish OB can project primary dendrites to several different, small (10–20 μm in diameter), and less well-defined glomeruli (Mori, K., 1995). However, the organization of the teleost OB may not be that radically different than in some mammals, since ~20% of the mitral cells in the main OB in rabbits possess multiple primary dendrites (Mori, K. *et al.*, 1983).

The anatomical organization in the teleost OB is similar to that observed in the accessory olfactory bulb (AOB) of the vomeronasal system in tetrapods where AOB mitral cells also have multiple apical dendrites, each of which innervates a small glomerulus (Satou, M., 1990; Takami, S. and Graziadei, P. P. C., 1991). This organization suggests that mitral cells in both the fish OB and the tetrapod AOB integrate odorant information from different types of ORNs (i.e., those expressing different molecular receptors) that provide input to the different glomeruli. A recent tracing study in the mouse, however, indicated that AOB mitral cells innervate glomeruli that only receive input from the same receptor type (i.e., a homotypic connectivity) (Del Punta, K. *et al.*, 2002). It is currently unknown whether such a homotypic connectivity is characteristic of the teleost OB (Satou, M. *et al.*, 1983; Riddle, D. R. and Oakley, B., 1992). Depending on the particular species of teleost, the anatomical organization within the OB can vary. For example, a recent investigation of the zebrafish OB indicated that the majority (~80%) of the mitral cells observed possessed a single primary apical dendrite (Fuller, C. L. *et al.*, 2005).

The dendritic field of a single mitral cell in fish can extend for more than 300–400 μm from the soma (Kosaka, T. and Hama, K., 1982b; Oka, Y., 1983) and terminate either in discrete tufts or in diffuse, brush-like ending (Kosaka, T. and Hama, K., 1982b; Riddle, D. R. and Oakley, B., 1992). However, in spite of this extensive dendritic field, the neuronal activities on one side of the OB are not influenced much by those in the opposite side (Satou, M., 1990), suggesting that there is little crossing of dendritic fields to opposite sides of the bulb. The recent evidence for odotopy within the OB of channel catfish (Nikonov, A. A. and Caprio, J., 2001) supports the functional isolation between right and left OB. In other aspects, mitral cells within fish lack basal dendrites, and thus, lateral interactions between mitral cells occur at the bases of their primary dendrites (Ichikawa, M., 1976; Kosaka, T. and Hama, K., 1982a; Oka, Y., 1983). Furthermore, axons of fish mitral cells arise not only from cell bodies but from thick dendrites (Dryer, L. and Graziadei, P. P. C., 1994). Ruffed neurons, a cell type not observed in tetrapods, are also located within the mitral cell layer in teleosts. These cells synapse with granule cells but not with ORNs (Kosaka, T. and Hama, K., 1979; 1981). Tufted and periglomerular cells are apparently lacking in the teleost OB (Satou, M., 1990; Dryer, L. and Graziadei, P. P. C., 1994).

4.04.4.2.2 Extrabulbar pathway

Although the vast majority of axons of ORNs project to the OB, in some teleosts, a small subset ORN axons pass through the OB and project directly to the ventromedial telencephalon (Bazer, G. T. *et al.*, 1987; Honkanen, T. and Ekstrom, P., 1990; Szabo, T. *et al.*, 1991; Riddle, D. R. and Oakley, B., 1992; Becerra, M. *et al.*, 1994; Hofmann, M. H. and Meyer, D. L., 1995). Little functional information is known about this extrabulbar primary olfactory pathway (Fujita, I. *et al.*, 1991), but it is distinct from that of the terminal nerve (CN 0) whose axons also pass through the OB and connect to specific forebrain (FB) nuclei (Demski, L. S. and Northcutt, R. G., 1983).

4.04.4.2.3 Odotopic representation of odorants in the teleost olfactory bulb

Indication that the teleost OB is divided into different zones, each processing a specific class of biologically relevant odor, was initially indicated by Thommesen G. (1978), based on the recording of local field potentials in salmonids. This study showed that the lateral OB was highly responsive to amino acids, whereas the medial OB was more selective to bile acids/salts. Other evidence came from anatomical studies also in a salmonid (rainbow trout) that olfactory information arriving at the OB from the olfactory epithelium was likely sorted chemotopically (Riddle, D. R. *et al.*, 1993) and not topographically (Riddle, D. R. and Oakley, B., 1991). More direct evidence for the existence of an odotopic map in the teleost OB was derived from additional investigations of field potential in salmonids (Døving, K. B. *et al.*, 1980; Hara, T. J. and Zhang, C., 1996), calcium (Friedrich, R. W. and Korsching, S. I., 1997; Fuss, S. H. and Korsching, S. I., 2001) and voltage (Friedrich, R. W. and Korsching, S. I., 1998) imaging of olfactory nerve terminals within the OB of zebrafish, and a single-unit study in the OB of the channel catfish (Nikonov, A. A. and Caprio, J., 2001). The exceptional optical imaging study of odor responses to amino acids of olfactory receptor terminals within glomeruli of the lateral OB in zebrafish (Friedrich, R. W. and Korsching, S. I., 1997) provided the direct evidence that both odor identity and concentration

are encoded by combinatorial glomerular activity patterns (Buck, L. B., 1996). Although some variations exist across the species of teleosts investigated, the general results of these studies indicate that food-related odors (i.e., amino acids and nucleotides) are mapped in OB regions (generally in the lateral OB) distinct from those of more socially relevant odors (bile salts, bile acids, and pheromones), which are mapped generally in the medial OB (Sorensen, P. W. *et al.*, 1991; Nikonov, A. A. and Caprio, J., 2001).

The medial–lateral distinction in odotopy within the teleost OB is consistent with mitral cell axons of the medial and lateral OB, respectively, projecting into the medial and lateral olfactory tracts (OTs) (Sheldon, R. E., 1912; Satou, M., 1990). The neuronal activities on one side of the fish OB are not influenced much by those on the opposite side, which is explained by limited dendritic fields of neurons in each part of the OB (Satou, M., 1990). In this respect, electrical stimulation experiments of distinct bundles of the OT in salmonids (Døving, K. B. *et al.*, 1980) and goldfish (Stacey, N. E. and Kyle, A. L., 1983; Demski, L. S. and Dulka, J. G., 1984) and behavioral investigations in crucian carp that had selected transections of different OT bundles (Hamdani, E. H. *et al.*, 2000; 2001a; 2001b; Weltzien, F. *et al.*, 2003) also support the previous evidence for a functional (food-related versus socially related) division between the medial and the lateral OB. This functional separation between types of odorants processed in medial and lateral OB is in sharp contrast to the two mirror-symmetric glomerular maps that exist in rodents (Lodovichi, C. *et al.*, 2003).

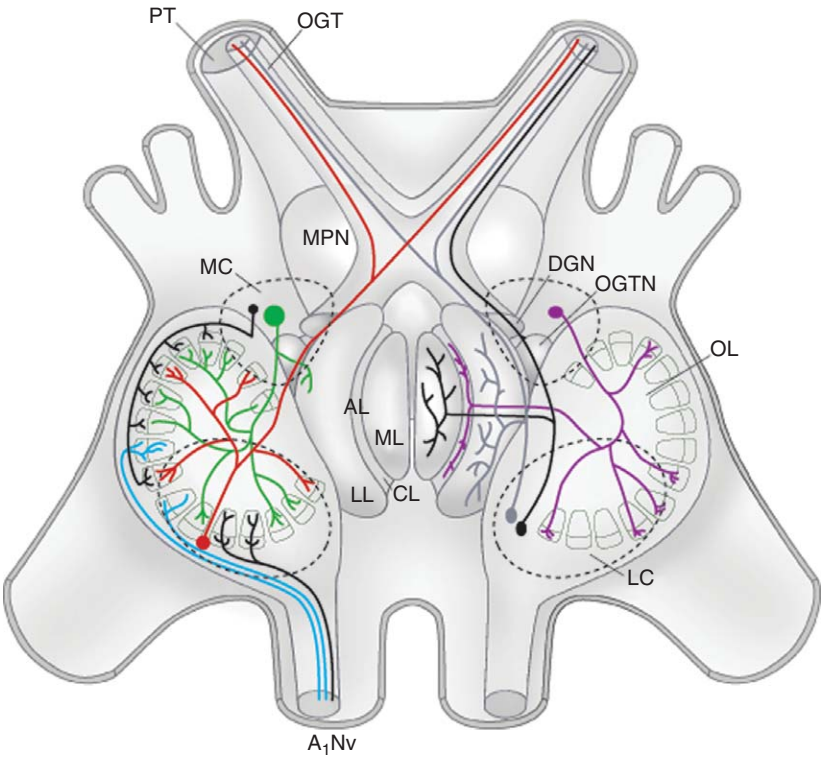
4.04.4.2.4 Odorant specificity of single olfactory bulb neurons

Electrophysiological investigations within the OB of the channel catfish (Nikonov, A. A. and Caprio, J., 2004) and zebrafish (Friedrich, R. W. and Laurent, G., 2004) provided information concerning the excitatory response spectrum to amino acids of single neurons (likely mitral cells) at the first synaptic level in the teleost olfactory system. Since the axons of ORNs expressing like ORs converge in the OB onto specific target glomeruli (Ressler, K. J. *et al.*, 1994; Vassar, R. *et al.*, 1994; Mombaerts, P. *et al.*, 1996; Strotmann, J. *et al.*, 2000), it is likely even in fish that the mitral cells whose apical dendrites innervate the respective glomeruli are tuned to odorants similarly as the ORNs that provide the input, but modified by intraglomerular circuitry (Yokoi, M. *et al.*, 1995; Sachse, S. and Galizia, G., 2002).

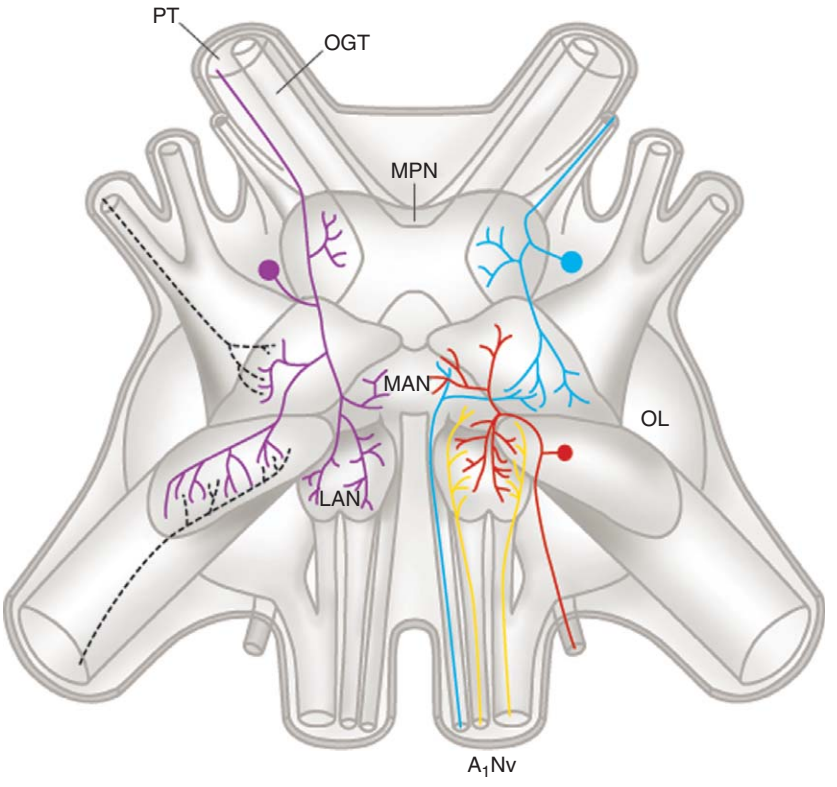
Two groups of neurons were recently identified in the OB of the channel catfish that were excited by amino acids. Group I OB neurons ($n = 91$ (37%)) were highly specific to the type of amino acid, that is, excited by acidic, basic, or neutral (those possessing short and long side chains, respectively) amino acids, and group II OB neurons ($n = 154$ (63%)) were also excited by a second amino acid but only at $\geq$10 times higher odorant concentration (Nikonov, A. A. and Caprio, J., 2004). Tested with an expanded series of amino acids, a subset of the group I OB units that were selective for neutral amino acids also distinguished neutral amino acids possessing long linear side chains from those with branched side chains. With increasing stimulus concentration, however, responses broadened such that single OB neurons responded selectively to neutral amino acids having either linear or branched side chains, but not to amino acids with either acidic or basic side chains. These results are consistent with the identification of relatively independent molecular ORs for acidic, basic, and neutral amino acids that were previously indicated in teleosts from electrophysiological cross-adaptation (Caprio, J. and Byrd, R. P., Jr. 1984; Caprio, J., *et al.* 1989; Sveinsson, T. and Hara, T. J., 1990; Michel, W. C. and Derbidge, D. S., 1997), biochemical binding (Cagan, R. H. and Zeiger, W. N., 1978; Brown, S. B. and Hara, T. J., 1981; Rhein, L. D. and Cagan, R. H., 1983; Rehnberg, B. G. and Schreck, C. B. 1986; Lo, Y. H. *et al.*, 1991), and calcium imaging (Friedrich, R. W. and Korsching, S. I., 1997; Fuss, S. H. and Korsching, S. I., 2001) studies. Relatively independent ORs for neutral amino acids with short and long side chains, respectively, were also reported (Caprio, J. and Byrd, R. P., Jr. 1984; Bruch, R. C. and Rulli, R. D., 1988; Sveinsson, T. and Hara, T. J., 1990).

It is rather intriguing that recent electrophysiological data obtained in zebrafish also provide evidence for OB unit selectivity to the type of amino acid prior to a reported declustering of odor representations that occurred over the first 800 ms of the response (Friedrich, R. W. and Laurent, G., 2001; Laurent, G. *et al.*, 2001). However, a similar effect was not observed in OB unit responses in channel catfish analyzed over a 3 s response period (Nikonov, A. A. and Caprio, J., 2004). Of 78 group I units analyzed from the OB of the channel catfish (i.e., those that were originally determined to be selectively responsive to only Met, Ala, Arg, or Glu over 3 s of response), 81% and 85% were similarly classified when analyzing the first and third seconds of the responses, respectively (Nikonov, A. A. and Caprio, J., 2004). A reanalysis (Caprio, J., unpublished data) was performed of zebrafish OB unit responses over the initial 400 ms of the response as reported in Figure 3 of Friedrich R. W. and Laurent

(a) Antennular olfactory pathway



(b) Antennular nonolfactory chemosensory pathway



G. (2004) using the catfish scheme of identifying different groups of units by their selected excitatory responses to a specific type of amino acid. The results of this analysis suggested that 49 of the 58 units (84%) could be arranged into the same groups as had been reported for catfish – that is, those units that were preferentially excited by acidic, basic, short-chain neutral, and long-chain neutral amino acids. In addition, a fifth group emerged that was not detected in the channel catfish, those responsive to aromatic amino acids. Of these 49 zebrafish OB units, 63% were similarly classified when analyzing their responses over the first 1 s of the response, and 45% were similarly classified when the analysis time included 1.4 s of the response. These results suggest that there were not profound changes in responses of mitral cells in the zebrafish to the type of amino acid over response time and that the gradual dissolution of responses to types of amino acids over response time is possibly due to adaptational processes. For the zebrafish studies, however, the interpretation of the data is that responses of the population of mitral cells change over time in a stimulus-specific manner, thus providing a mechanism for the behavioral discrimination of individual amino acids (Friedrich, R. W. and Laurent, G., 2001). At present, the two different interpretations of the experimental results remain disputable.

Recently, the specificity of single OB units in the channel catfish to bile salts was reported (Rolen, S. H. and Caprio, J., 2007). OB neurons were identified that were excited selectively by taurine-conjugated bile salts and nonconjugated bile salts, respectively. A third type of OB neuron was rather nonselective and was excited by at least one member of each of three types of bile salts: taurine-conjugated, glycine-conjugated, and nonconjugated.

4.04.4.2.5 Olfactory forebrain

The OB odotopic maps of the aforementioned species of teleosts provide a blueprint for investigation of the organization of odor processing at the next ascending synaptic level in the olfactory system. The axons of the output neurons of the OB (i.e., mitral and ruffed cells) constitute the medial and lateral OTs, which terminate in the cerebral lobes of the olfactory FB. A critical question is whether an odor map exists in the FB, and if so, whether its organization is based on odorant structure as it is in the OB and the antennal lobe of insects. An alternate possibility is that an FB map is not based on odorant quality but on odorant function (e.g., feeding or social odorant cues), or even, that due to the apparent extensive overlap of medial and lateral OT projections, a chemotopic map may not exist in the FB.

Recent experiments performed to visualize FB neurons in mice (Zou, Z. *et al.*, 2001; 2005) and mushroom body and lateral horn neurons of the protocerebrum in *Drosophila* (Wong, A. M. *et al.*, 2002; Marin, E. C. *et al.*,

Figure 3 Antennular chemosensory pathways in the brain of spiny lobsters. (a) Summary diagram of the olfactory (aesthetasc) pathway, which is a ventral view of the brain. The olfactory lobe (OL) receives input from aesthetasc olfactory receptor neurons (ORNs) via the main antennular nerve (A_1Nv). ORNs typically terminate in a single glomerulus (blue), though there may be multiglomerular ORNs (black). The OL has two general types of interneurons: projection neurons (PNs), with their somata in the lateral somata cluster (LC); and local neurons (LNs), with their somata in the medial somata cluster (MC). Three types of OL interneurons are shown, distinguished according to color (red, black, and gray). In red is a PN with multiglomerular innervation in the OL and an axon that bifurcates and extends via the olfactory globular tracts (OGTs) to higher-order neuropils. Two types of OL LNs are shown (purple and green). The accessory lobe (AL) is organized into three regions: medial lobe (ML), central lobe (CL), and lateral lobe (LL). The AL receives no direct sensory input from receptor neurons, but it does receive input from the OL via LNs. AL LNs (purple), similar to those of the OL, have somata in the MC. The AL has PNs (black and gray), which are similar to PNs of the OL in having somata in the LC and bifurcated processes that exit the brain via the OGTs. The deutocerebral commissure neuropil (DCN) and olfactory globular tract neuropil (OGTN) are also innervated by processes from OL interneurons. (b) Summary diagram of the nonolfactory (nonaesthetasc) pathway, which is a dorsal view of the brain. Nonaesthetasc antennular chemoreceptor neurons (CRNs) and antennular mechanoreceptor neurons (yellow) project via the antennular nerve (A_1Nv) into the ipsilateral LAN. The LAN has two regions: a lateral lobe and a medial lobe. There is a general topotopy, in that receptor neurons from the antennular lateral flagellum innervate the lateral lobe of the LAN, and receptor neurons from the antennular medial flagellum innervate the medial lobe of the LAN. These receptor neuron terminals overlap with arborization of the antennular motor neurons (red). The MAN receives mechanoreceptor input via the A_1Nv from the statocyst (blue), an organ for maintaining equilibrium. PNs of the LAN leave the brain via the protocerebral tract (PT). The tegumentary neuropil (TN) and antennal neuropil (AnN) receive sensory input (dashed black) from the second antenna (A_{II}Nv). (a) is adapted from Schmidt, M. and Ache, B. W. 1996b. Processing of antennular input in the brain of the spiny lobster, *Panulirus argus.* II. The olfactory pathway. J. Comp. Physiol. A 178, 605–628. (b) is adapted from Schmidt, M. and Ache, B. W. 1996a. Processing of antennular input in the brain of the spiny lobster, *Panulirus argus.* I. Non-olfactory chemosensory and mechanosensory pathway of the lateral and median antennular neuropils. J. Comp. Physiol. A 178, 579–604. Courtesy: Amy Horner.

2002) that receive input from specific glomeruli of the OB (mice) or antennal lobe (*Drosophila*) provided a consistent picture of the general organization of OT projection patterns and suggested the possible logic for olfactory information processing in these brain structures. Common to both mice and *Drosophila* was a stereotypic projection of secondary olfactory projection neurons from specific glomerular modules of the OB or antennal lobe that terminate with considerable overlap in their multiple brain target areas. The recent findings that projection classes with similar axon terminal fields in the lateral horn in *Drosophila* tended to receive input from neighboring glomeruli (Marin, E. C. *et al.*, 2002) and that structurally similar odorants in the honeybee (Sachse, S. *et al.*, 1999), zebrafish (Friedrich, R. W. and Korsching, S. I., 1997), and rodents (Tsuboi, A. *et al.*, 1999; Malnic, B. *et al.*, 1999; Strotmann, J. *et al.*, 2000; Uchida, N. *et al.*, 2000) likely activate adjacent and overlapping glomeruli of the OB or antennal lobe suggest an odotopic organization in these central olfactory processing centers. However, recent studies indicated that this map in higher-order olfactory centers is different from that within the OB or antennal lobe (Zou, Z. *et al.*, 2001; 2005; Marin, E. C. *et al.*, 2002; Wong, A. M. *et al.*, 2002). Thus, in contrast to the OB, axonal arborizations in FB are diffuse and extensive, and projections from different OB glomeruli often overlap to varying degrees. This anatomical organizational pattern suggests that third-order neurons in the olfactory pathway integrate odor information arriving from multiple OB glomeruli, which possibly codes for odorant quality and which may also relate to the odor's behavioral significance (e.g., food or pheromones) (Johnson, D. M. G. *et al.*, 2000; Haberly, L. B., 2001; Wang, Y. *et al.*, 2001; Zou, Z. *et al.*, 2001; Marin, E. C. *et al.*, 2002; Wong, A. M. *et al.*, 2002).

For channel catfish, an FB odotopic map resembling somewhat that present in the OB was recently determined (Nikonov, A. A. *et al.*, 2005; Nikonov, A. A. and Caprio, J., 2007). Both the medial–lateral distinction between excitatory responses to bile salts and amino acids and the rostrocaudal distinction between excitatory responses to amino acids and nucleotides reflect a similar topographical organization within the OB of the same species. The amino acid-responsive terminal field appears homologous to the olfactory cortex and perhaps the olfactory tubercle, whereas the bile salt-responsive region, the medial terminal field, is possibly homologous to portions of the amygdala in amniote vertebrates (Wullimann, M. F. and Rink, E., 2002; Wullimann, M. F. and Mueller, T., 2004; Nikonov, A. A. *et al.*, submitted). Furthermore, as suggested by the previous anatomical investigations of possible convergence within the FB of OT fibers emanating from different OB glomeruli, cell types not previously observed within the OB were evident. These included units that were excited by both amino acids and nucleotides and others excited by both neutral and basic amino acids; however, there was no evidence of the convergence of odor information arriving via the separate medial and lateral OTs. Thus, convergence occurred between OT fibers providing input of food-related odorants, but not between food-relevant and socially relevant chemical signals.

4.04.4.3 Crustaceans

4.04.4.3.1 Organization of the olfactory lobes

CRNs of the antennules are packaged into a diversity of types of sensilla (see Section 4.04.3). One of these types is specialized as the olfactory sensilla – the aesthetascs. The ORNs of the aesthetascs project ipsilaterally to the paired OL (Schmidt, M. and Ache, B. W., 1996b) (Figure 3). The OLs are thought to receive input almost exclusively from aesthetasc ORNs (Schmidt, M. and Ache, B. W., 1992; 1996b; Sandeman, D. C. *et al.*, 1992).

The OLs have a glomerular organization (Figure 3), generally similar to first-order olfactory neuropils of other animals – the antennal lobes of insects and the OBs of vertebrates (Hildebrand, J. G. and Shepherd, G. M., 1997; Strausfeld, N. J. and Hildebrand, J. G., 1999; Eisthen, H. L., 2002; Schachtner, J. *et al.*, 2005). The neuronal components of the OL glomeruli are also generally similar to that of the olfactory neuropils of vertebrates and insects. Besides the primary afferent input from the aesthetasc ORNs, there are projection interneurons (PNs), several classes of local interneurons (LNs), and centrifugal neurons. The location of the somata associated with these neurons is precise: the LNs have their somata in the medial cluster (cluster 9), and the PNs have their somata in the lateral cluster (cluster 10). The OL glomeruli have clear subdivisions: cap, subcap, and basal regions. These regions contain different neuronal types and synaptic interactions (Schmidt, M. and Ache, B. W., 1996b; Wachowiak, M. *et al.*, 1997). Most ORNs branch in only one glomerulus, primarily in the cap and subcap regions (Schmidt, M. and Ache, B. W., 1992). PNs have multiglomerular projections, with dense innervation in a few glomeruli and sparse

innervation in many (Schmidt, M. and Ache, B. W., 1996b). The centrifugal fibers synapse on the somata of OL interneurons and are probably modulatory in function (Schmidt, M., 1997). The glomerular cap region is innervated by only two types of neurons: ORNs and multiglomerular GABAergic LNs. This implies that there are synapses between these neuronal types. This is probably the basis for the presynaptic inhibition from LNs onto ORNs (Wachowiak, M. *et al.*, 2002). Presynaptic inhibition in the OB also occurs in the vertebrates (Wachowiak, M. *et al.*, 2002).

Inhibition within the OL is mediated through at least two overlapping but functionally distinct inhibitory pathways (Wachowiak, M. and Ache, B. W., 1997). These are based on GABA and histamine, which shape the odor responses of OL units (Wachowiak, M. and Ache, B. W., 1998). These inhibitory circuits may have functional correlates with lateral inhibitory pathways in antennal lobe of insects and OB of vertebrates (Ache, B. W., 2002).

The number of OL glomeruli drastically varies across crustaceans, ranging from about 150 to 1300. The basis for this range is not obviously related to the number of aesthetascs, the animal's habitat, or phylogeny (Beltz, B. S. *et al.*, 2003).

Additionally, no clear sexually dimorphism in OLs is known, unlike has been described in some insects (e.g., the macroglomerular complex). This is in spite of the fact that sex pheromones are known in many crustaceans and their reception is mediated by aesthetascs (Gleeson, R. A., 1991; Kamio, M. *et al.*, 2002). It is possible that the OL possesses pheromone-specific glomeruli, but they are not morphologically distinct at a gross level.

Given findings that the glomerular organization in insects and vertebrates reflects odotopic mapping, it might be expected that the crustacean OL also has odotopic maps. There is indirect evidence for this, based on the fact that each aesthetasc expresses a diversity of ORNs (Steullet, P. *et al.*, 2000b) and the axons of ORNs from a single aesthetasc projects to many if not most glomeruli (Mellon, D. Jr. and Munger, S. D., 1990; Mellon, D. Jr. and Alones, V., 1993). The relationship between the number of ORNs and number of OL interneurons is instructive. For example, in spiny lobsters, each aesthetasc has ~300 ORNs (Derby, C. D. *et al.*, 2003). Aesthetascs appear to be functional units, with similar sets of ORNs in each aesthetasc (Steullet, P. *et al.*, 2000b); however, the number of different types of OR genes or ORNs is not known. Even assuming that there are 300 different types of ORs or ORNs, more than one type of ORN must innervate each glomerulus. However, direct tests of this hypothesis are lacking. Additionally, there is extensive convergence, given that there young adult spiny lobsters have about 300 000 ORNs per antennule projecting into 1200 glomeruli containing about 200 000 PNs and 100 000 LNs (Schmidt, M. and Ache, B. W., 1996b; Schachtner, J. *et al.*, 2005).

Closely associated with the OL, but lacking any primary sensory input, are the paired accessory lobes (ALs), olfactory globular tract neuropils, and deutocerebral commissure neuropils (Wachowiak, M. *et al.*, 1996; 1997; Sandeman, D. and Mellon, D., 2001; Ache, B. W., 2002; Schachtner, J. *et al.*, 2005) (Figure 3). The ALs are notable because of their large size in lobsters and crayfish and their glomerular organization. However, the AL glomeruli are smaller, more numerous, and of different synaptic organization than the OL glomeruli (Wachowiak, M. *et al.*, 1996; Schmidt, M. and Ache, B. W., 1996b). ALs have three regions – medial, central, and lateral – and each with specific synaptic connections (Wachowiak, M. *et al.*, 1996; Ache, B. W., 2002). For example, the medial and lateral regions have PNs, and the central region has interneurons connecting the AL to the OL as well as connection to the medial and lateral regions of the AL through LNs. The function of the AL is unknown, though its variance in size in different groups of crustaceans provides some grounds for speculation (Sandeman, D. C. *et al.*, 1993; Ache, B. W., 2002).

4.04.4.3.2 Organization of other chemosensory neuropils

All other antennular CRNs besides those in the aesthetascs, which include those on both the lateral and medial flagella of the antennules, project ipsilaterally to the paired LANs and to the unpaired MAN (Schmidt, M. and Ache, B. W., 1996a) (Figure 3). The LANs and MAN have a laminated organization, not glomerular. Unlike the OLs, the LANs and MAN also receive projections of mechanosensory neurons and antennular motor neurons. This organization is suggestive of topotopic maps, where space along the antennule is mapped topographically onto these neuropils (Schmidt, M. and Ache, B. W., 1993; 1996a; Schachtner, J. *et al.*, 2005); however, critical data are lacking.

4.04.4.3.3 Higher-order processing centers

The output interneurons from the OLs, ALs, and LANs project via the olfactory–globular tract (Figure 3) to a region of the protocerebrum called the terminal medulla and hemiellipsoid bodies, which are probably functionally equivalent to the mushroom bodies and lateral horn of insects (Schachtner, J. *et al.*, 2005). But the interneurons from the OLs, LANs, and ALs terminate in different regions of these neuropils, with phylogenetically diverse patterns of connection (Sullivan, J. M. and Beltz, B. S., 2004; 2005). The functional significance of these different projections and the activity of neurons in these higher-order neuropils are being explored (Sandeman, D. and Mellon, D., Jr. 2001; McKinzie, M. E. *et al.*, 2003).

4.04.4.3.4 Other chemoreceptor neuron processing centers

Virtually nothing is known about central processing of CRNs from the legs or mouthparts, except the identity of the regions into which their receptors project (e.g., Weissburg, M. J. *et al.*, 2001). While it is appreciated that the leg and mouthpart pathways control different behaviors than do the antennules (Derby, C. D., 2000; Horner, A. J. *et al.*, 2004; Garm, A. *et al.*, 2005), the mechanisms responsible for these differences remain largely unexplored.

4.04.4.4 Overview

The first-order olfactory processing center in both fishes and crustaceans, as with other vertebrates and arthropods, is glomerular in organization. These are the OB and AOB of fish, and the OL of crustaceans. The glomeruli are clusters of neuropil that contain the synapses between inputs (ORNs), outputs (mitral cells in fishes, projection neurons in crustaceans), and local interneurons. ORNs have ipsilateral projections, most being uniglomerular. The glomerular organization reflects an odotopy, with the odorants, at least food-related odorants, being represented across the glomeruli in a combinatorial fashion. Synaptic interactions within the OB and OL, which include inhibitory lateral connections, shape neuronal responses such that the output neurons of the OB and OL have different quality and temporal and response characteristics.

4.04.5 Neurogenesis and Turnover of Olfactory Neurons in Adult Crustaceans

Many crustaceans, fortunately including the model organisms for chemosensory research such as spiny lobsters, clawed lobsters, and crayfish, have indeterminate growth and add new ORNs to their olfactory organ and local and output interneurons to the OLs in the brain, throughout life including as adults (Steullet, P. *et al.*, 2000a; Harzsch, S., 2001; Derby, C. D. *et al.*, 2001a; Harrison, P. J. H. *et al.*, 2001a; Schmidt, M. 2001; Beltz, B. S. and Sandeman, D. C., 2003; Sandeman, R. and Sandeman, D., 2003).

Olfactory neurogenesis is highly flexible. Its rate can be modulated in adaptive ways by many variables. For example, following damage to the antennule, ORN neurogenesis increases dramatically so as to quantitatively compensate for the damage (Harrison, P. J. H. *et al.*, 2001a; 2003; 2004). As well, damage to the antennule modulates the rate of neurogenesis of olfactory interneurons (Sandeman, R. *et al.*, 1998; Hansen, A. and Schmidt, M., 2001; Sandeman, R. and Sandeman, D., 2003). Neurogenesis can also vary with internal factors, such as molt stage that is controlled by steroid hormones (Harrison, P. J. H. *et al.*, 2001a; 2001b), and environmental factors, such as circadian cycle (Goergen, E. M. *et al.*, 2002), season (Hansen, A. and Schmidt, M., 2004), environmental richness (Sandeman, R. and Sandeman, D., 2000), and social experience (Beltz, B. S. and Sandeman, D. C., 2003; Sandeman, R. and Sandeman, D., 2003; Song, C.-K. *et al.*, 2004).

In addition to continuous neurogenesis, olfactory neurons in the antennule, and to some extent in the brain, continuously turn over (Sandeman, R. and Sandeman, D. C., 1996; Steullet, P. *et al.*, 2000a; Schmidt, M., 2001; Harrison, P. J. H. *et al.*, 2001a; 2001b; 2003; 2004). The functional impact of this is that the olfactory organ completely turns over its ORNs after approximately four to five molts; the time for this depends on factors such as size of animal and environmental conditions, but for a young adult spiny lobster, this is approximately 1 year (Steullet, P. *et al.*, 2000a; Harrison, P. J. H. *et al.*, 2001a). The antennule is fully functional at any time, although the most proximal (newest) and distal (oldest) regions of aesthetascs have fewer aesthetascs and, at least in the case of the proximal (immature) aesthetascs, are not or less responsive to odors (Steullet, P. *et al.*, 2000a; 2000b). ORNs may be immature for several weeks or

more after their birth (Steullet, P. *et al.*, 2000a; Harrison, P. J. H. *et al.*, 2001a), and olfactory interneurons may be immature (defined by typical expression of neurochemicals) for several months (Schmidt, M., 2001).

The fact that the site of proliferation of new ORNs is in a very small area of the olfactory organ gives experimental advantages of using crustacean models over others in exploring aspects of olfactory neurogenesis. For example, candidate molecules involved in ORN proliferation can be identified by using techniques such as representational difference analysis to identify transcripts that are enriched in the region of ORN proliferation compared to regions of mature ORNs. Initial analyses of this kind have identified interesting candidates (Stoss, T. D. *et al.*, 2004). These include (1) one whose expression levels also increase following damage, which also upregulates neurogenesis; (2) a member of the same protein family as follistatin, which is an antagonist of GDF 11, and GDF 11 is expressed by progenitors of mammalian ORNs and whose absence prevents proliferation of ORNs (Wu, H.-H. *et al.*, 2003); and (3) a growth factor of the PDGF/VEGF family. RT–PCR approaches (Chien, H. *et al.*, 2005) have also identified *splash*, a spiny lobster homologue of achaete-scute genes, and which is expressed in regions of ORN neurogenesis in the olfactory organ. Since the mammalian achaete-scute homologue, MASH, is involved in differentiation of ORNs in rodents, *splash* is an interesting initial candidate in the exploration of molecular mechanisms of control and modulation of olfactory neurogenesis in crustaceans.

4.04.6 Taste in Fish

4.04.6.1 Peripheral Taste Anatomy

Taste buds in teleosts are located generally on the lips and within the oral cavity, including high densities on the gill rakers (Jakubowski, M. and Whitear, M., 1990; Sorensen, P. W. and Caprio, J., 1998; Finger, T. E., and Simon, S. A., 2000; Hansen, A. and Reutter, K., 2004) (Figure 4). The buds can be elevated on epidermal hillocks, be flush with the surrounding epidermis, or sunken. Taste buds are also found on the external body surface, primarily on the face and in some species, such as catfishes, along the entire external body surface (Reutter, K., 1978). This increase in extraoral taste buds is thought not to result directly in an increase in sensitivity but in a greater ability to localize a taste source (Bardach, J. E. *et al.*, 1967). Taste bud densities can vary tremendously depending on the species, the location of the receptive field, and the size of the specimen. In some fishes, such as minnows and certain cyprinids, up to ~300 taste buds mm^{-2} were estimated (Gomahr, H. *et al.*, 1992). Teleost taste

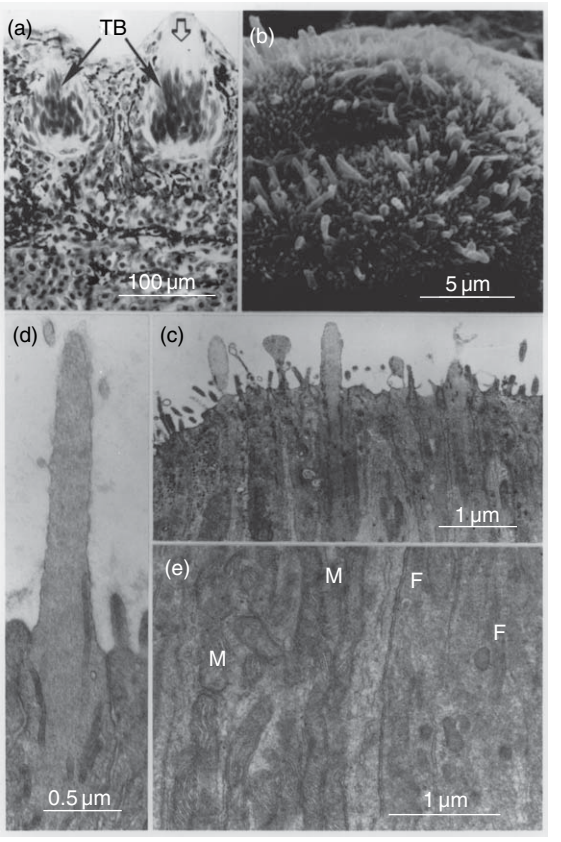


Figure 4 Teleost taste buds. (a) Light micrograph of a longitudinal section through two maxillary barbell taste buds of the bullhead catfish, *Ameiurus nebulosus*. TB indicates two taste buds and cells within; these taste buds are of the elevated type (unfilled arrow). At the lower portion of each taste bud, basal cells are observed. (b) Scanning electron micrograph (SEM) of a portion of the surface of a catfish (*Ameiurus*) taste bud showing numerous small and fewer large receptor microvilli. (c) Transmission electron micrograph (TEM) of the apical portion of an *Ameiurus* taste bud in longitudinal section. The apical portion of the light cells forms a single large receptor villus of a light cell and a small villus of an adjacent dark cell in longitudinal section from a *Silurus glanis* (European Wels catfish) taste bud. (e) Detail of the supranuclear region of a longitudinally sectioned *Silurus* taste bud that shows numerous mitochondria (M) within a light cell (left) and bundles of intermediate filaments (F) in a dark cell (right). Reprinted from Sorensen, P. W. and Caprio, J. 1998. Chemoreception. In: The Physiology of Fishes (ed. D.H. Evans), pp. 375–405. CRC Press LLC, by courtesy of Taylor and Francis Group, LLC. Courtesy: Klaus Reutter.

buds contain up to ~100 cells that are generally divided into three types: light, dark, and basal cells (Reutter, K., 1978; Jakubowski, M. and Whitear, M., 1990). Light cells, considered the actual taste cell, possess a single large (0.5 µm thick, 1.5–3 µm long) club-shaped microvillus at its apical surface, whereas dark cells, which partially wrap light cells, have at their apical surface numerous small (0.1–0.2 µm thick, 0.5–1.0 µm long) microvilli and are considered supporting cells. However, dark cells in some species (e.g., ictalurid catfishes) form synapses with basal cells and may function also as taste cells (Reutter, K., 1978). Serotonin-rich basal cells, which resemble Merkel cells, number up to ~5 per taste bud, are oriented transversely to the longitudinal axis of the taste bud at the basal pole and form synaptic contacts with presumed taste cells. As in land vertebrates, taste cells undergo turnover. However, since teleosts are poikilothermic, the rate of turnover is dependent on the ambient water temperature. At temperatures of 14, 18, 22, and 30 °C, taste cells in channel catfish have an average life span of 40, 30, 15, and 12 days, respectively (Raderman-Little, R., 1979). Also, as in other vertebrates, taste buds, depending on their location, are innervated by branches of either the VII, IX, or X CN. In addition to taste cells located within taste buds, teleosts can possess solitary chemosensory cells (SCCs), which resemble taste receptor cells that reach densities in excess of $100\,000\,\mathrm{mm}^{-2}$ and, depending on the location on the fish, form synaptic contact with different afferent nerve fibers (V, VII, and spinal) (Kotrschal, K., 1991; 1993; Finger, T. E., 1997; Hansen, A. and Reutter, K., 2004). Furthermore, there can be considerable overlap between input to the CNS of both SCC and gustatory neurons as in rocklings *Ciliata* and *Gaidropsarus* (Teleostei: Gadidae), or the SCC input via spinal nerves can be quite distinct from the taste system as in searobins (*Prionotus carolinus*) (Finger, T. E., 1982; Kotrschal, K. and Finger, T. E., 1996). These anatomical differences in central connections suggest that the SCCs of rocklings and searobins are not homologous. Physiological studies on SCCs are scant, but they suggest that SCCs in rocklings respond primarily to body mucus of heterospecific fish (Peters, R. C. *et al.*, 1991).

4.04.6.2 Taste Cell Physiology and Transduction

The major class of taste stimuli studied in a wide variety of fish species is amino acids, although additional gustatory stimuli investigated in particular species include small peptides, nucleotides, bile salts and acids, aliphatic acids, quaternary ammonium compounds, and steroids (Marui, T. and Caprio, J., 1992; Hara, T. J., 1993). High-affinity taste receptor sites for L-alanine (dissociation constant (K_D) of 1.5 µM) and L-arginine (two affinity states: K_D values of 18 nM and 1.3 µM), respectively (Caprio, J., *et al.*, 1993), are located primarily on different taste cells within the same taste bud (Finger, T. E. *et al.*, 1996). The existence of independent gustatory receptor sites for L-alanine and L-arginine in channel catfish was determined previously from both electrophysiological and biochemical studies; a low-affinity receptor site for L-proline was also indicated (Caprio, J. *et al.*, 1993). Current evidence suggests that these three major classes of amino acid taste receptors in the channel catfish are coupled to activation of the taste receptor cells by two different mechanisms. At micromolar concentrations, L-alanine activates a G-protein-dependent increase in IP_3 or cAMP, but with a more rapid IP_3 production (Kalinoski, D. L. *et al.*, 1989). In contrast, both L-arginine and L-proline appear to be directly coupled to the activation of nonselective, but independent, cation channels (Kumazawa, T. *et al.*, 1998; Grosvenor, W. *et al.*, 2004). Further evidence of nonrandom expression of these amino acid taste receptors on taste cells is from electrophysiological studies of single taste fibers in the channel catfish, which has identified fiber types in the facial taste system that are highly responsive to L-alanine and L-arginine, respectively (Kohbara, J. *et al.*, 1992), and fiber types highly responsive to L-alanine, L-arginine, and L-proline, respectively, in the glossopharyngeal taste system (Ogawa, K. and Caprio, J., unpublished data).

Specific information concerning the molecular nature of taste receptors in vertebrates and the identification of their ligands has recently become available. As in mammals (Zhang, Y. *et al.*, 2003), fishes express two families of G-protein-coupled receptors, T1Rs and T2Rs in separate taste cells (Ishimaru, Y. *et al.*, 2005). T1Rs, members of class C GPCRs that possess an extensive N-terminus, exist as dimers. T1R dimers in fish detect amino acids (either T1R1/3 or multiple T1R2/3s), whereas T2Rs, which possess a short extracellular N-terminus and have not been shown to exist as dimers, detect bitter tastants (Oike, H. *et al.*, 2007).

4.04.6.3 Peripheral Nerve Taste Responses

Among the fishes tested electrophysiologically with amino acids, two groups were identified (Hara, T. J.

and Zielinski, B., 1989; Hara, T. J., 1993): (1) those whose facial taste system (those taste buds innervated by facial (CN VII) nerve fibers) responded to a number of different amino acids (i.e., wide response range) as demonstrated by channel catfish (Caprio, J., 1975; 1978) and (2) those whose facial taste systems were more selective (i.e., limited response range) as seen in salmonids (Hara, T. J. and Zielinski, B., 1989; Hara, T. J. *et al.*, 1999). Furthermore, multiunit recordings demonstrate that different branches of the facial nerve innervating different populations of taste buds located in different anatomical locations on the body of the fish have similar response properties and selectivities (Caprio, J., 1978; Davenport, C. J. and Caprio, J., 1982; Kanwal, J. S. *et al.*, 1987). The data are usually analyzed by comparing the magnitude of the integrated neural taste responses to the different chemicals at the same concentration. The relative magnitude of the integrated taste responses obtained even from different CNs can be similar as observed in rainbow trout (Kohbara, J. and Caprio, J., 2001). However, in other species such as channel catfish, taste responses between facial and glossopharyngeal/vagal nerves can be quite distinct (Kanwal, J. S. and Caprio, J., 1983; Kohbara, J. *et al.*, 1992). Facial taste thresholds for specific amino acids ranged generally between nano- and micromolar. Furthermore, depending on the species studied, taste thresholds of IX/X nerve fibers to specific amino acids can be either similar or higher than that determined for facial taste responses (Kanwal, J. S. and Caprio, J., 1983; Kohbara, J. and Caprio, J., 2001). Taste thresholds estimated from recordings from IX and/or X nerves in channel catfish were higher than those for VII, which is logical considering that high taste sensitivity of taste buds within the oropharyngeal cavity is not essential because of the higher stimulus concentrations present in the mouth once food intake occurs (Kanwal, J. S. and Caprio, J., 1987). The L-isomer of an amino acid was significantly more stimulatory than its D-isomer. However, a population of facial taste fibers in the sea catfish, *Arius felis*, was described that was more responsive to D- than to L-alanine (Michel, W. and Caprio, J., 1991) (see next section). In some fishes, sensitivity to a particular non-amino acid stimulus may even be greater than it is to amino acids. For example, the facial taste system of the rainbow trout to a bile salt, taurolithocholate, approaches picomolar concentrations, which is 4 log units lower than for L-proline, the most stimulatory amino acid (Hara, T. J. *et al.*, 1984; Yamashita, S. *et al.*, 2006).

4.04.6.4 Processing Taste Information by Single Peripheral Taste Fibers

Since taste receptor cells are secondary receptors, they must synapse with afferent nerve fibers (VII, IX, or X) to transmit gustatory information to the primary gustatory nucleus of the medulla. A single taste fiber may synapse with multiple taste cells, not all of which are necessarily located in the same taste bud. For example, in channel catfish, the number of taste buds innervated by a single taste fiber of the recurrent facial nerve that innervates taste buds on the flank increases with the size of the fish, from two taste buds per axon in small fish (~5 cm in length) to nearly 14 taste buds per axon profile in larger fish (37–40 cm) (Finger, T. E. *et al.*, 1991). Information on the processing of taste information by peripheral nerve fibers in teleosts is extremely limited and is based primarily on quantitative analyses of responses of facial taste fibers in only a few species. The data obtained with amino acid stimuli from these species, however, indicate that there is sufficient similarity in the tuning characteristics of gustatory neurons to justify the existence of different fiber types.

Although single-unit studies of the taste specificity of teleosts were accomplished in only a few species of the more than 25 000 that exist, some tentative generalizations can be drawn:

1. Taste information concerning different classes of taste stimuli can be transmitted to the medulla by different groups (i.e., types of facial taste fibers); for example, the facial taste system of Japanese puffer fish (*Fugu pardalis*) consists of different populations of taste fibers with specificities to amino acids, nucleotides, and an inorganic acid, respectively (Kiyohara, S. *et al.*, 1985).
2. The specificity of a single taste fiber is not limited to a particular class of chemical stimuli; for example, one taste fiber type in the yellowtail flounder is highly responsive to both a nucleotide (uridine-5′-monophosphate) and an amino acid (L-tryptophan) (Zeng, C. and Hidaka, I., 1990).
3. Different taste fiber types having widely different tuning to members of the same class of chemicals can exist within the same CN of a particular species; for example, populations of facial taste fibers with different amino acid specificities occur in channel catfish (Kohbara, J. *et al.*, 1992; Caprio, J., *et al.*, 1993), sea catfish (Michel, W. and Caprio, J., 1991), Japanese puffer (Kiyohara, S. *et al.*, 1985), and yellowtail (Zeng, C. and Hidaka, I., 1990).
4. Taste fibers of different CNs (VII versus IX and X) within the same species can have different chemical

specificities; for example, a population of taste fibers highly responsive to L-proline occurs for the IX but not VII taste system in channel catfish (Ogawa, K. and Caprio, J., unpublished data).

5. The proportion and types of taste fibers comprising different CNs can vary within the same species; for example, the population of L-alanine taste fibers within the IX taste nerve in channel catfish was reduced by 55% compared with VII.
6. In addition to the existence of populations of taste fibers that are highly responsive to particular L-amino acids, taste fibers for D-amino acids may also exist; for example, 38% of the single facial taste fibers analyzed from the sea catfish, *Arius felis*, were most responsive to D-alanine (Michel, W. and Caprio, J., 1991). However, this fiber type also responded to L-alanine, and the L-alanine fiber type responded to D-alanine. High concentrations of D-amino acids occur in the tissues of soft-bodied invertebrates (Preston, R. L. 1987), potential prey items of the sea catfish. In contrast, only 3% of the single facial taste fibers in the freshwater channel catfish were most responsive to D-alanine (Kohbara, J. *et al.*, 1992).
7. Irrespective of the of the chemical specificity of the particular taste fiber types occurring in a species, stimulus quantity appears to be coded by the frequency of action potentials generated. For individual taste fibers, some have a dynamic response range of 5–6 log units of stimulus concentration, whereas other fibers, even in the same fish, have more truncated dose–response relations (Michel, W. and Caprio, J., 1991; Kohbara, J. *et al.*, 1992).
8. Some peripheral taste fibers in a particular species may be bimodal, that is, they respond to both taste and mechanical stimuli as in catfish (Davenport, C. J. and Caprio, J., 1982; Ogawa, K. *et al.*, 1997), whereas in other species, such as the Japanese puffer, this does not appear to be the case (Kiyohara, S. *et al.*, 1985).

4.04.6.5 Taste and Tactile Input to the Central Nervous System (Medulla)

Chapter 10 in this volume and a previous report (Kanwal, J. S. and Finger, T. E., 1992) provide excellent reviews of the gustatory pathways within the CNS of teleosts. This section is thus limited to a brief summary of the topographical manner in which taste and tactile information is represented in the primary gustatory nucleus of the medulla of catfishes since much of the limited information on the processing of taste information was derived from these teleosts known for their elaborate gustatory system. Limited electrophysiological information also exists concerning taste and tactile activity in higher-order, that is, pontine (Lamb, C. F. IV and Caprio, J., 1992) and diencephalic (Lamb, C. F. IV and Caprio, J., 1993), gustatory nuclei in catfish but is beyond the scope of this review.

Taste and tactile information (see point 8 above) arriving via VII and IX/X terminates in register and in a somatotopic and viscerotopic manner, respectively, within the special visceral sensory column of the rostral medulla that is equivalent to the gustatory portion of the nucleus of the solitary tract in mammals. Both taste and tactile information from the external body surface and rostral oral cavity in catfishes is processed within the facial lobe (FL) of the medulla and that within the more posterior oral cavity and gill rakers by the glossopharyngeal nucleus (possibly a small lobe in some species) and vagal lobe (VL) (Finger, T. E., 1976; Kanwal, J. S. and Caprio, J., 1987). There is, however, a disproportionate representation of structures (e.g., an enlarged volume of medulla for the representation of barbels and gill rakers), which is indicative of their relative functional importance for taste and tactile input. The FL, through its input from external body taste buds and its interconnections to the spinal cord and medullary reticular formation, is involved in localization of a stimulus and controlling swimming behavior (Kanwal, J. S. and Finger, T. E., 1997). As such, the FL map is well defined and precise. The glossopharyngeal and vagal systems, which receive input from taste buds within the oral cavity, in contrast connects with brainstem nuclei in the control of swallowing and oropharyngeal movements (Atema, J., 1971; Finger, T. E. and Morita, Y., 1985). The VL map is not so important for the localization of food and is thus more diffuse than that of the FL (Kanwal, J. S. and Caprio, J., 1988).

For teleosts that possess specialized taste and tactile structures, such as barbels, the special visceral column can be subdivided into two to three lobes (Kanwal, J. S. and Finger, T. E., 1992). Within each lobe a finer representation of body parts (e.g., barbels and gill arches) can be represented in lobules (Kanwal, J. S. and Caprio, J., 1987; Hayama, T. and Caprio, J., 1989; Kiyohara, S. and Caprio, J., 1996). For catfishes, taste and tactile inputs from each of the different barbels project to a different lobule within the FL (Kiyohara, S. *et al.*, 1986; Kanwal, J. S. and Caprio, J., 1988; Marui, T. *et al.*, 1988). In addition to

the existence of peripheral bimodal (taste and tactile) fibers, mechanosensory input into the primary gustatory nucleus also occurs via mechanosensory-only facial (Davenport, C. J. and Caprio, J., 1982; Kiyohara, S. *et al.*, 1985) and trigeminal (Kiyohara, S. *et al.*, 1986) fibers. Medullary neurons responsive to taste stimuli (i.e., amino acids) were limited to smaller areas of the electrode tracks than neurons sensitive to touch alone (Marui, T., 1977; Marui, T. and Funakoshi, M., 1979; Marui, T. and Caprio, J., 1982; Kanwal, J. S. and Caprio, J., 1988). The overlap of taste and tactile maps is interesting from a neuroethological aspect as both types of input are involved in the detection and selective food ingestion in catfish and are likely processed simultaneously prior to activation of the respective motor neurons.

4.04.7 Processing of Mixtures

4.04.7.1 Introduction

In all natural environments, including aquatic, olfactory and gustatory receptor cells rarely encounter single pure chemicals as are usually presented in experimental studies. The composition of many biologically relevant mixtures in aquatic environments, particularly of food, is well characterized (Carr, W. E. S., 1988). Behavioral studies demonstrate the high potency of animal extracts and mixtures of amino acids to fishes and crustaceans. Additionally, however, the magnitude of the response to a chemical mixture is poorly predicted from knowledge of the responses to the individual components – revealing mixture interactions. These are either mixture suppression or mixture enhancement, in which the response to the mixture is less or greater, respectively, than expected. Obviously then, defining the expected response to a mixture becomes the critical issue. To do so for a CRN, it is critical to know several of its features: Does a CRN have both excitatory and inhibitory transduction pathways? Does a CRN have more than one type of receptor? If so, how are these coupled to the excitatory and/or inhibitory transduction pathways? Which mixture components interact with each receptor and transduction pathway? How do those components interact with the receptors – that is, are they agonists or antagonists, and is their action competitive or noncompetitive?

The more completely characterized is the cell, the more accurate is the predicted response to a mixture. In other words, mixture interactions are a consequence of an incomplete understanding of the above processes.

Fish and crustaceans, especially catfish and spiny lobsters, serve as model organisms to understand how mixtures are processed. These studies are built largely on electrophysiological and biochemical studies that have defined the diversity of receptor types and transduction pathways at the cellular level. Arguably, our understanding of how the sensory systems of animals detect, process, and ultimately lead to the discrimination and perception of mixtures is as complete for catfish and lobsters as it is for any animal. (And sadly, we still have a long way to go!) This section summarizes our understanding of mixture processing in these systems.

4.04.7.2 Fish

4.04.7.2.1 Introduction

Electrophysiological studies in teleosts attempted to predict the global response, that is, olfactory EOG (electro-oculography) and olfactory and gustatory integrated neural activity (Hidaka, I. *et al.*, 1976; Caprio, J., *et al.* 1989; Kohbara, J. and Caprio, J., 1996; Ogawa, K. and Caprio, J., 2000) to simple (binary and ternary) mixtures of amino acids. Additionally, a single olfactory electrophysiological investigation studied responses to complex mixtures (up to 10 components) of amino acids (Kang, J. and Caprio, J., 1991). The overall results of these investigations indicated that knowledge of the relative independence of the receptors for the component stimuli in a mixture, obtained from receptor binding and/or electrophysiological cross-adaptation experiments, was essential to successfully predict the magnitude of the electrophysiological response. Mixtures whose components showed little competition or cross-adaptation generated responses greater than those whose components were indicated to compete with a common receptor or with receptors having highly overlapping specificities. There was little evidence for mixture suppression. That mixture interactions are weak in the peripheral olfactory system in teleosts was also indicated in the zebrafish (Tabor, R. *et al.*, 2004). For olfaction, where single ORNs express one or at most a few ORs (Ngai, J. *et al.*, 1993; Mombaerts, P. 2004), the greater response to a mixture of amino acids was likely due to the activation of multiple populations of ORNs, each ORN within a specific population expressing one of the receptors for a particular component in the mixture. The greater response to mixtures observed in the peripheral taste system was also likely due to the activation of different receptors wherever expressed; for this effect observed in single taste fibers in the channel catfish (Ogawa, K. and Caprio, J., 1999) and Japanese puffer (Hidaka, I. *et al.*,

1976), the different receptors could theoretically be located on individual cells within a single taste bud or on different taste cells in different taste buds innervated by the single taste fiber. These studies also indicated for both olfactory and gustatory systems that the greater responses to mixtures are more likely due to the simultaneous activation of different receptors by the individual components of the mixture than by stimulus binding at the same total concentration to a single receptor. The greater response to a mixture whose components bind to relatively independent receptors than to a single or highly cross-reactive receptors may be the electrophysiological correlate of the behavioral observations that mixtures are often more stimulatory than individual components, even in cases when the concentration of the individual component is higher than the total concentration of the multiple-component stimuli within the mixture.

4.04.7.2.2 Responses of single units

4.04.7.2.2.(i) Olfaction There are few quantitative physiological studies of how single olfactory neurons in fishes respond to stimulus mixtures – primarily amino acids. For teleosts, only in the channel catfish was a quantitative study of single ORNs performed to stimulus mixtures (Kang, J. and Caprio, J., 1997), whereas responses of single OB neurons to stimulus mixtures were investigated in both the channel catfish (Kang, J. and Caprio, J., 1995b; 1997; Tabor, R. *et al.*, 2004) and zebrafish (Tabor, R. *et al.*, 2004). For channel catfish, the types of responses of single ORNs and OB neurons to binary mixtures comprising components that were either both excitatory, both suppressive, or both nonresponsive were similar (based on response type) to those of the components in 80% (for ORNs) and 82% (for OB neurons) of the trials. These results are comparable to a similar study in rats where 75% of the responses of single OB neurons to binary mixtures evoked similar response patterns as the components of the binary mixtures (Giraudet, P. *et al.*, 2002). Overall, these results indicate that profound mixture interactions are rare in simple mixtures where the components evoke similar responses.

For simple binary mixtures where the responses to the components were different (i.e., excitatory (E) and nonresponsive (N); suppressive (S) and N; E + S, respectively), responses of catfish OB neurons to the mixture were often similar in 94% of the trials to that for one of the components (Kang, J. and Caprio, J., 1995b). For example, in a binary mixture of an excitatory and a suppressive component, the response of an OB neuron to the mixture was either excitatory or suppressive in 94% of the trials – in only 6% of the trials was the mixture nonresponsive. For catfish ORNs, responses to the mixtures were similar to that for one of the components in 82% of the trials for E + S mixtures and 100% for both E + N and S + N mixtures (Kang, J. and Caprio, J., 1997). In a comparable study in the OB of the rat, units evoked a similar pattern of response, as did one of the components in the mixture in 83% of the trials (Giraudet, P. *et al.*, 2002). For zebrafish OB units, where binary mixtures of amino acids comprised an excitatory and a suppressive component ($n = 18$), the response to the binary mixture was dominated (in 85% of the cases) by the excitatory response, whereas the suppressive component occurred in the remaining 17% of the trials. In additional experiments, the component responses and those to the binary mixtures were complex, differing primarily in their temporal patterns (Tabor, R. *et al.*, 2004). In contrast, for OB units in channel catfish where excitatory and suppressive responses to the mixture components tested were equivalent (29%; 42% null), the response to the binary mixture was excitatory in 34%, suppressive in 41%, and null (no response significantly different from control) in 25% of the trials ($n = 32$) (Kang, J. and Caprio, J., 1995b). Mixture suppression or masking, where a component reduced or concealed the neuron's excitatory or inhibitory response to the other component, however, was observed with single ORN and OB neurons in catfish and single OB neurons in rat. This effect was observed when there was no significant response to a binary mixture composed of an effective stimulus (evoking either an E or S response) and a nonstimulatory component. Such mixture suppression occurred in 62% (for E + N components) and 68% (for S + N components) of these trials in catfish ORNs, 43% in catfish OB neurons, and 46% in rat OB neurons (when analyzing firing rates).

4.04.7.2.2.(ii) Taste Electrophysiological responses of integrated and single-unit facial taste responses to binary mixtures of amino acids in the channel catfish (Ogawa, K. and Caprio, J., 1999) were consistent with previous olfactory results obtained in the same species (see above). These reports collectively indicate that the magnitude of multiunit responses to binary and more complex olfactory and gustatory stimulus mixtures is greater if the component stimuli bind to relatively independent receptor sites than to the same or highly cross-reactive sites. The study also indicated that the greater taste activity observed to the mixture was not significantly different, whether

recording the taste activity in a multifiber or a single--unit preparation. This finding is noteworthy in indicating that greater taste activity is not exclusively the result of the components in a binary mixture simultaneously activating different fiber types (i.e., having different chemical specificities); that is, the greater response also occurred by the activation of different taste receptors on taste cells innervated by the same single taste fiber. Also indicated was that the magnitude in enhanced taste activity could be significantly different across the different responding gustatory fiber types. In the Japanese puffer, *F. pardalis*, the amino acid derivative betaine (*N*-trimethyl glycine) enhanced taste activity of facial taste fibers to particular amino acids (Hidaka, I. *et al.*, 1976).

4.04.7.2.3 Behavioral discrimination

Fish are similar to humans in that components of binary mixtures are discriminable. Humans can identify up to approximately three components in either taste (Laing, D. G. *et al.*, 2002) or olfactory mixtures (Laing, D. G. and Francis, G. W., 1989). Whether a binary mixture of amino acids is detected by fishes as a unique odor or whether the qualities of the individual components are retained within the mixture was investigated in catfish (Valentinčič, T. *et al.*, 2000a). It was previously determined for catfish that the discrimination of chemicals is based on olfaction and not on taste (Valentinčič, T. *et al.*, 1994). Catfish conditioned to a binary mixture initially treat the mixture as the component eliciting the greater physiological response (based on the magnitude of the EOG in response to each component). This result is similar to that for humans, where binary odor mixtures are perceived as the more stimulatory component (Laing, D. G. and Willcox, M. E., 1983). Additional discrimination training in catfish, however, facilitates the discrimination of the less potent component in a binary mixture – that is, the binary mixture is no longer detected as its more stimulatory component. Thus, with enough training, catfish are able to elementally process mixtures (i.e., identify the separate components of the mixture).

4.04.7.3 Crustaceans

4.04.7.3.1 Electrophysiology

Electrophysiological studies of processing of mixtures by crustaceans have been performed exclusively using single cells rather than global responses such as EOGs. Thus, explanations are possible at the single-cell level as well as at the system level through analysis of populations of these single cells.

Single CRNs of crustaceans have multiple transduction pathways, including excitatory and inhibitory pathways and including more than one receptor type in the excitatory pathway (see Section 4.04.2). Thus, when trying to understand the response to a mixture, even a simple one such as a binary mixture, the magnitude and direction of the response (i.e., increase or decrease from spontaneous spiking rate) will depend on whether the components of a mixture activate the excitatory or the inhibitory pathway and on whether they activate the same or different receptor sites in a given pathway. As a consequence, responses to mixtures can be either more or less than the more excitatory component. The following are some examples.

If a CRN has both excitatory and inhibitory transduction pathways, and one chemical activates the excitatory pathway and another chemical activates the inhibitory pathway, then we would expect that a mixture of these two chemicals would generate a response less than excitatory chemical and greater than the inhibitory chemical. This has been observed from intracellular whole-cell patch clamp recording from lobster CRNs (Michel, W. C. and Ache, B. W., 1992). This type of effect can explain some cases of mixture suppression identified from extracellular measurement of spiking activity of single-unit recordings from lobster CRNs. These CRNs often have very low levels of spontaneously spiking activity – often much less than 1 spike per second – so that if a compound activates an inhibitory transduction pathway, this inhibition is not expressed as a reduction in spiking activity. If only spiking activity were being recorded, this would lead to an identification of mixture suppression. Yet knowing the transduction cascades activated by these components of a mixture leads to a predicted response that matches that observed.

If a CRN has two receptors types, each coupled to an excitatory transduction pathway as seems to be the case for many CRNs of crustaceans (see Section 4.04.2), then it is important to know how the components of a mixture interact with these receptor types. The predicted responses are different if the mixture components bind primarily to the same receptor or bind to different receptors. If the components compete for the same receptor, then whether they are competitive agonists or antagonists will influence the response generated by the mixture. The clearest demonstration of this is in a study by Cromarty S. and Derby C. (1997). This study examined responses

of taurine-sensitive CRNs to binary mixtures of excitatory compounds, either competitive agonists (taurine and structural analogues of taurine) or noncompetitive agonists (taurine and structurally dissimilar molecules). Responses to binary mixtures of competitive agonists were significantly lower than responses to mixtures of noncompetitive agonists, but they were exactly that expected from a competitive model. Knowing how these compounds bind to receptors and how these receptors are coupled to transduction cascades allowed accurate predictions of responses to mixtures; without this, mixture interactions would be suggested to have occurred.

As described in the next section, behavioral studies suggest that spiny lobsters can use elemental processing to analyze mixtures, such that the mixture is perceived as a set of identifiable components (Livermore, A. *et al.*, 1997). This behavioral finding has implications on how mixtures are processed by the peripheral olfactory system. It suggests that a mixture and its components should generate different neural response profiles and that the response profile of the mixture should have features in common with its components. In addition, if one component of a mixture dominates the perception of a mixture, then the neural profile generated by the mixture should be more similar to that of the dominant component. These ideas were tested using different blend ratios of binary mixtures (Steullet, P. and Derby, C. D., 1997). The results suggest that for the neural profiles generated in the peripheral olfactory system of spiny lobsters, the qualities of individual compounds are maintained when the compounds are mixed to form blends. This result suggests a neural explanation of the ability of spiny lobsters to elementally process an odor mixture.

4.04.7.3.2 Behavior

Mixture interactions have been examined at the behavioral level in some detail in several crustacean species, including the glass shrimp *Palaemonetes pugio* (Carr, W. E. S. and Derby, C. D., 1986a; 1986b), the Caribbean spiny lobster *P. argus* (Derby, C. D. *et al.*, 1989; Daniel, P. C. and Derby, C. D., 1991), the California spiny lobster *Panulirus interruptus* (Zimmer-Faust, R. K. *et al.*, 1984; Zimmer-Faust, R. K., 1987; 1993), and the American lobster *H. americanus* (Borroni, P. F. *et al.*, 1986; Atema, J. *et al.*, 1989). In these studies, typically the magnitude of the behavioral response (usually an appetitive response) to a mixture is compared to that of the responses to that mixture's components. The response magnitudes are then compared to each other and to the predicted responses calculated on a variety of models that fall into two classes: (1) those that assume the components interact with the same transduction pathways and (2) those that assume the components activate independent transduction pathways. The outcomes of these studies differ. For the glass shrimp, mixture enhancement or synergism, in which the mixture response was significantly greater than expected, was common. Compounds that by themselves had no activity, when mixed with each other or with compounds that were moderately active, generated very strong responses. Using an antennular flicking assay on the Caribbean spiny lobster and binary mixtures of compounds, mixture suppression was much more common, in which the response to a binary mixture was less than expected. In the California spiny lobster, adding a repellent compound (ammonium) to an attractive compound (ATP) predictably produced a response to the mixture that was less than that to the attractant alone (Zimmer-Faust, R. K. *et al.*, 1984; Zimmer-Faust, R. K., 1987; 1993). From these results, it is clear that predicting responses to mixtures based only on responses to components is unreliable. We have argued earlier that with detailed knowledge of the transduction pathways within an ORN and the chemical stimuli that activate each of them, accurate predictions of mixture responses are possible. But of course for behavior, many neuronal levels exist between ORNs and motor output, including complex synaptic interactions. For example, some mixture interactions occur at the level of the CNS, independent of the ORNs (Derby, C. D. *et al.*, 1985). Thus, generating a better understanding of processing of chemical information in the CNS is essential for understanding the behavior of animals to mixtures.

The ability of lobsters to discriminate among chemical stimuli is known from studies using aversive paradigms similar to those used on other animals. Such associative conditioning generates an aversive response to one chemical stimulus, even one previously attractive, and then animals can be examined for response generalization to other stimuli (Fine-Levy, J. B. *et al.*, 1988). This procedure was used for several sets of stimuli that were also used in electrophysiological studies of mixture processing (see below). These include single compounds; binary mixtures that differ only in blend ratios, and their components; and complex mixtures of 29–35 components that mimic their natural food (crab, shrimp, oyster, and mullet). These results show that lobsters show the greatest generalization between stimuli that are closest in composition. For example,

lobsters show much more generalization between crab mixture and shrimp mixture than between other mixtures, and this is highly correlated with the degree of similarity in the blend ratios of these mixtures (Fine-Levy, J. B. *et al.*, 1988; 1989; Fine-Levy, J. B. and Derby, C. D., 1991).

Behavioral studies also showed that spiny lobsters perceive chemical mixtures in different ways, depending on the salience of the components. They can learn them as a set of elemental cues if the salience of the components during learning is sufficiently high. In addition, they can also learn them as a configural cue (i.e., as a mixture-unique entity) if the salience of the individual components is not emphasized (Livermore, A. *et al.*, 1997; Derby, C. D., 2000).

4.04.7.4 Overview

Catfish and spiny lobsters are two of the more intensely studied animals regarding the neural processing and behavioral responses to chemical mixtures, and as such, they provide excellent case studies. Behavioral studies show that both catfish and spiny lobsters perceive the components of binary and even larger mixtures as discriminable elements, if the salience or relevance of those components is emphasized. This implies elemental processing. If the salience of the components is not emphasized, then mixtures are perceived as a configural (i.e., mixture-unique) cue. This leads to the conclusion that each discriminable component of a mixture should generate a unique neural profile, at least at early processing levels. Electrophysiological studies on catfish and lobsters support this conclusion. Individual studies identified examples of mixture interactions, in which the response to the mixture is different from that expected from the response to the mixture's components. However, the body of work on catfish and spiny lobsters demonstrates that the more completely characterized is a cell or a system, the more accurate is the predicted response to a mixture. If one knows the receptor types, the transduction cascades, how receptor types are coupled to those cascades, and which chemical stimuli interact with each receptor type and transduction cascade, then by using rigorous experimental procedures, responses to mixtures are highly predictable. A few studies on catfish and lobsters demonstrate this (Caprio, J., *et al.*, 1989; Kang, J. and Caprio, J., 1991; Cromarty, S. and Derby, C., 1997). The challenge is of course to build a detailed understanding of all of these molecular pathways. Since mixtures are the biologically relevant stimuli for animals, this is more than a worthy endeavor, as difficult as it is.

4.04.8 Behavioral Roles of Olfaction and Taste

4.04.8.1 Introduction

The chemical senses are involved to some degree in many behaviors of fishes and crustaceans. These include finding food, mates, habitat, and shelter, avoiding predators, social interactions, and homing. Although many studies investigated the chemosensory behavior of different species to chemical stimuli, the vast majority did not determine which chemosensory systems – olfaction, taste, or others – were primarily responsible for the behavioral results. Since both olfactory and taste systems for particular species of fishes and crustaceans can be highly sensitive to specific classes (e.g., amino acids) of chemical stimuli (Caprio, J., 1978; Goh, Y. and Tamura, T., 1980; Hara, T. J., 1994), without the appropriate controls, it can be confusing as to which system or systems are responsible for releasing a specific behavioral response.

4.04.8.2 Fish

Olfaction is involved in the detection and search for food and is uniquely implicated in the detection of pheromones and other chemicals that provide information concerning sex, social interactions, alarm, and homing. Taste, on the other hand, is also associated with food-related behaviors, but those that are more of a reflexive nature, such as ingestion, biting, and swallowing of food; for catfishes, taste also participates directly in the localization of the food source (Hara, T. J., 1993; Sorensen, P. W. and Caprio, J., 1998).

Typical feeding stimulants of fishes are amino acids, and both the olfactory and gustatory systems are generally highly stimulated by amino acids. However, the chemical specificity and the specific functions of the two chemosensory systems to these compounds can be quite distinct (Caprio, J., 1977; Goh, Y. and Tamura, T., 1980; Kohbara, J. *et al.*, 1992; Nikonov, A. A. and Caprio, J., 2004), and the feeding behaviors controlled by the two are not identical but are overlapping. For a generic fish (i.e., one without an elaborate extraoral taste system) such as rainbow trout, both olfactory (Hara, T. J., 1973) and gustatory (Marui, T. *et al.*, 1983) systems can be highly sensitive to amino acids. However, anosmic

rainbow trout are incapable of initiating feeding in response to these chemical cues, in spite of a fully functioning taste system (Valentinčič, T. and Caprio, J., 1997). In contrast, for catfishes, which possess extensive extraoral and oral taste systems and a concomitant increase in the neural circuitry of the medulla facial and VLs to process gustatory information, both food search and ingestion are released in anosmic specimens (Bardach, J. E. *et al.*, 1967; Valentinčič, T. and Caprio, J., 1994). Olfaction in catfishes, however, is essential for the discrimination of different amino acid stimuli in a learning paradigm (Valentinčič, T. *et al.*, 1994; 2000b; Valentinčič, T., 2004).

4.04.8.3 Crustaceans

There are differences, as well as some overlap, in those behaviors controlled by olfaction (aesthetascs) and taste. In spiny lobsters, the antennules drive detection of and orientation to distant, attractive chemicals, including food-related chemicals and intraspecific chemicals such as aggregation pheromones and alarm pheromones (Derby, C. D. *et al.*, 2001b; Horner, A. J. *et al.*, 2004; Shabani, S. and Derby, C. D., 2006) and pheromones (aggregation cue and alarm cues) (Horner, A. J. and Derby, C. D., 2005; Shabani, S. and Derby, C. D., 2006). Interestingly, either the aesthetasc (olfactory) pathway alone or the nonaesthetasc antennular pathway alone is sufficient to mediate the animal's response to food odors (Horner, A. J. and Derby, C. D., 2005; Shabani, S. and Derby, C. D., 2006). In addition, both of these pathways can mediate discrimination of and learning about food-related chemicals, be they single compounds, simple mixtures, or complex mixtures. Thus, there is considerable redundancy between the aesthetasc and the nonaesthetasc antennular pathways. However, differences in the functions of the aesthetasc and nonaesthetasc antennular pathways have been identified as well. For example, only the aesthetasc pathway, and not the nonaesthetasc antennular pathway or extra-antennular chemosensory pathway, mediates attraction to aggregation pheromones or alarm pheromones (Horner, A. J. *et al.*, 2004; Horner, A. J. and Derby, C. D., 2005; Shabani, S. and Derby, C. D., 2006). "Aesthetases are also necessary for the response of clawed lobsters to social odors (Johnson, M. E. and Atema, J., 2005)". Thus, the aesthetascs uniquely possess detectors of aggregation and alarm cues.

It must be emphasized that although we have placed the nonaesthetasc antennular sensors in a single category, they differ not only structurally but also functionally. On the antennular flagella, there are nine different types of nonaesthetasc sensilla (Cate, H. S. and Derby, C. D., 2001). Although they all are bimodally innervated by chemosensory neurons and mechanosensory neurons that project to the LANs, they differ in setal structure and organization and in location on the antennule (Cate, H. S. and Derby, C. D., 2001; 2002). They also differ in function. For example, the asymmetric sensilla are uniquely responsible for mediating chemically activated antennular grooming behavior (Schmidt, M. and Derby, C. D., 2005).

Chemosensors on the legs of lobsters differ structurally and functionally from antennular sensory. In lobsters, they direct local searches to food chemicals, and when the leg touches the source of the chemicals, that item is grabbed and transferred to the mouthparts (Derby, C. D. and Atema, J., 1982).

Mouthpart chemoreceptors, with their high threshold and broad tuning (Garm, A. *et al.*, 2005), control whether food should be eaten (Derby, C. D. and Atema, J., 1982). Presumably they are checking the quality of the prey, such as determining whether feeding stimulants are present and deterrents are absent.

The hierarchy of control of behaviors by the different chemosensors as described above for lobsters may not apply completely to all crustaceans. For example, in the blue crab *Callinectes sapidus*, leg chemoreceptors can also play a role in orientation to distant cues (Keller, T. A. *et al.*, 2003).

Crustaceans demonstrate several types of learning involving their chemical senses, including habituation and aversive associative learning (Derby, C. D., 2000), one-trial flavor avoidance learning (hermit crab), and other important behaviors though less well-defined mechanistically (Caldwell, R. and Dingle, J., 1985; Wight, K. *et al.*, 1990). Aversive associative learning has been used to study spiny lobster's ability to discriminate chemical stimuli, including single-odorant compounds and different blend ratios of the same binary or complex mixtures (Derby, C. D., 2000). The associative task is learning to avoid a previously attractive food stimulus. Since this task is controlled by the antennules, expression of this learned task depends on the presence of fully functional antennules. But it does not require aesthetascs: either the aesthetasc (olfactory) pathway or the nonaesthetasc antennular pathway can mediate discrimination and learning about chemical stimuli (Steullet, P. *et al.*, 2001; 2002).

4.04.8.4 Overview

The chemical senses of fish and crustaceans control or modulate many of their behaviors. There are overlaps

and differences in the behaviors that are mediated by the different chemosensory systems, including olfaction and taste. Both olfactory and nonolfactory systems can mediate orientation to distant food-related chemicals. Olfactory systems tend to control detection of pheromones and thus cues associated with intraspecific interactions. Some of the behaviors controlled by olfaction include learning about chemicals involved in discrimination. Taste and other nonolfactory systems are uniquely associated with chemically activated biting and swallowing of food and other more reflexive behaviors.

Glossary

a-gustducin Alpha subunit of G protein-coupled receptor for bitter and sweet taste transduction pathways.

atypical mitochondria Large mitochondria with twisted-energized or swollen cristae found in Type II taste cells.

chorda tympani nerve Branch of the facial nerve (VIIth cranial) that innervates taste buds in the anterior two-thirds of the tongue.

circumvallate papillae Large, dome-shaped gustatory papillae located in the posterior one-third of the tongue; innervated by the glossopharyngeal nerve (IXth cranial).

facial nerve (Cranial nerve VII) Innervates taste buds fungiform and foliate papillae in the anterior two-thirds of the tongue.

foliate papillae Rows of gustatory papillae located on the sides of the posterior of the tongue; innervated by both the chorda tympani and glossopharyngeal nerve in rodents.

fungiform papillae Mushroom-shaped papillae located in the anterior two-thirds of the tongue; innervated by the chorda tympani nerve.

fusiform Spindle-shaped, with a wider center and tapered ends.

glossopharyngeal nerve Cranial nerve IX, which controls taste sensation in the posterior one-third of the tongue.

innervated Supplied with nerves.

intragemmal Located within the taste bud.

neurotropic Having an affinity for neural tissue, as in a neurotropic stain.

perigemmal Nerves that are found on the periphery of the taste bud.

pore substance Electron-dense material located in the taste pore of a taste bud.

subsurface cisternae Flat membranous stacks of smooth endoplasmic reticulum.

sustentacular taste cells Provides support or sustains.

umami Japanese word for delicious to describe the taste sensation when consuming amino acids such as glutamate.

vagus nerve Cranial nerve X, which innervated taste buds in the pharynx.

4.05.1 Introduction

Taste buds are onion-shaped end organs containing 50–150 cells that are specialized for detecting aqueous chemical stimuli. The taste bud is a dynamic system in which new taste cells (=taste bud cells) are continually being born, maturing, performing their sensory functions, eventually going into senescence, and ultimately dying – all within a period of from 10 days to 2 weeks (Beidler, L. and Smallman, R., 1965). However, recent evidence suggests that taste buds contain both long- and short-lived taste cells (Hamamichi, R. *et al.*, 2006). At the same time, the nervous system is believed to sprout new nerve processes and form synaptic connections with developing taste cells, while retracting synapses from old cells. Intragemmal taste cells are located within the taste bud proper, while perigemmal taste cells are located at the periphery of the taste bud. The goal of the present review is to provide the reader with a basic understanding of taste bud morphology.

Taste buds are surrounded by a relatively electron-dense, nongustatory epithelium replete with desmosomes, from which intermediate filaments project into the cytoplasm of the epithelial cells. The appearance of the nongustatory epithelial cells and the filamentous material is less organized near the basal region of the taste bud, making it more difficult to distinguish the basal region of the taste bud from the surrounding nongustatory epithelium. A typical mammalian taste bud is innervated by sensory nerve processes that enter at the base and ramify throughout the basal two-thirds of the taste bud. Nerve processes within a taste bud are termed intragemmal fibers. The intragemmal fibers originate from either the VII (facial), IX (glossopharyngeal), or the X (vagus) nerves (Figure 1). A small subset of taste cells form synapses onto the intragemmal nerve processes. Another set of nerve processes envelop but do not penetrate the taste bud; these are termed perigemmal nerves (however, see Nagy, J. *et al.*, 1982; Finger, T., 1986).

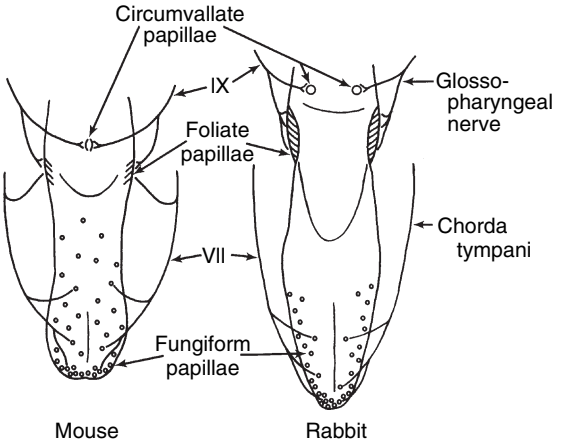

Figure 1 Innervation of rabbit and rat taste buds.

Although taste buds occur throughout the oral cavity, this review deals only with taste buds located on the foliate papillae of the rabbit and circumvallate taste buds of murines (rat and mouse). The rabbit foliate taste bud was selected because it was the first mammalian taste bud to be studied extensively and is the progenitor of the current system of taste cell classification. Taste buds of the rat and mouse were selected because these animals are the species of choice for physiological and molecular biology studies.

4.05.2 History

Taste bud structure has been studied for over a century, yet there is still considerable controversy concerning the classification of taste cells and an understanding of their functions (for reviews see Scalzi, H., 1967; Murray, R., 1973; Kinnamon, J., 1987; Roper, S., 1989; Reutter, K. and Witt, M., 1993; Miller, I., 1995; Finger, T., 1997; Pumplin, D. *et al.*, 1997; Finger, T. and Simon, S., 2000; Lindemann, B., 2001; Finger, T., 2005; Chandrashekar, J. *et al.*, 2006; Roper, S., 2006). The first descriptions of taste buds were in fish (Leydig, F., 1851). Mammalian taste buds were first studied by Schwalbe G. (1868) and Loven C. (1868). In the

nineteenth century taste on cells were named, classified, and ascribed functions based on their staining properties, especially to neurotropic stains such as methylene blue (e.g., Wilson, J. and Edin, M., 1905). Electron microscopy was first used to characterize taste bud ultrastructure over five decades ago (Engstrom, H. and Rytzner, C., 1956a; 1965b). Since then there have been numerous studies on taste bud ultrastructure of mammalian and nonmammalian species (Table 1). Ultrastructural criteria have been used to classify taste cells into various types, including undifferentiated peripheral cells, type I (dark) cells, type II (light) cells, type III (receptor) cells, type IV (basal) cells, and intermediate cells. Traditionally, the morphological criteria used to classify taste cells have included:

1. electron density of the cytoplasm;
2. nuclear shape;
3. types and distribution of nuclear chromatin;
4. accumulations of specific organelles (e.g., polyribosomes, granular and smooth endoplasmic reticulum, and Golgi bodies);
5. number, types, and arrangement of apical microvilli; and
6. presence of synapses onto nerve processes.

Some newer criteria include the presence of subsurface cisternae (SSCs) of smooth endoplasmic reticulum and large, atypical mitochondria with tubular cristae (Royer, S. and Kinnamon, J., 1988; 1994; Clapp, T. *et al.*, 2004).

4.05.3 A Classic Taste Bud: The Rabbit Foliate Taste Bud

The first ultrastructural studies on rabbit taste buds were carried out by Engstrom H. and Rytzner C. (1956a; 1956b) on foliate taste buds. They observed that taste cells had varying morphologies and staining properties, but found it difficult to classify the cells into different types. Because there appeared to be a continuum of cellular morphologies, Engstrom and Rytzner postulated that the different cell types represented stages of development of a single cell line. Since then the rabbit has been used extensively for ultrastructural studies on taste buds, most notably by Raymond Murray and coworkers (Murray, A., 1961; Murray, R. and Murray, A., 1966; 1967; Murray, R., 1969; Murray, R. *et al.*, 1969; Murray, R. and Murray, A., 1970; Murray, R., 1971; Murray, R. and Murray, A., 1971; Murray, R., 1973; Murray, R., 1986; Murray, R., 1993). The foliate papillae of a rabbit reside on both sides of the posterior tongue and contain numerous taste buds. These taste buds are innervated by branches of the glossopharyngeal nerve (IXth cranial nerve) (Murray, R. and Murray, A., 1971) as shown in Figure 1. This contrasts with the innervation of foliate papillae of the rat, which are innervated by branches of both the glossopharyngeal nerve and the chorda tympani branch of the facial nerve (VIIth cranial nerve) (Whiteside, B., 1927; Oakley, B., 1967).

As stated above, Engstrom H. and Rytzner C. (1956a; 1956b) did not classify rabbit foliate taste cells into specific types, postulating that the differing cellular morphologies represented stages of development of a single cell type. Later investigators began to classify rabbit taste cells into different types. Trujillo-Cenóz O. (1957) referred to neuroepithelial cells while De Lorenzo A. (1958; 1960; 1963) described receptor and sustentacular cells in rabbit foliate taste buds. Iriki T. (1960) classified taste cells from rabbit foliate taste buds as either gustatory or sustentacular. Murray A. (1961) observed two morphological cell types but eschewed the terms gustatory or sustentacular, instead proposing that both morphological cells types were gustatory in nature. Scalzi H. (1967), like Engstrom and Rytzner, supported the notion that there was most likely a single taste cell line in rabbit foliate taste buds, with cells differentiating from one cell type to another. This was reflected in the system of taste cell classification proposed by Scalzi, which included pregustatory, type Ia, type Ib, and type Ic taste cells. Murray R. and Murray A. (1967) described dark and light cells in rabbit foliate papillae, based primarily on the electron density of the cytoplasm. At that time, the light cell was believed to be the most likely candidate for being the gustatory receptor cell, but the dark cell was not completely excluded. Jeppsson P. (1969) adopted the dark and light cell nomenclature of Murray. In 1969 Murray and coworkers modified their system of classification for rabbit taste bud cells to include dark cells, light cells and introduced a new cell type – the type III or sensory cell (Murray, R., 1969; Murray, R. *et al.*, 1969; Murray, R., 1971). In addition, they adopted the type IV or basal cell proposed by Farbman A. (1965a) for rat taste buds. Following the nomenclature proposed by Farbman A. (1965a), Murray and coworkers referred to dark cells as type I cells, and light cells as type II cells. Iwayama T. (1970) and Fujimoto S. and Murray R. (1970) each carried out separate degeneration/regeneration studies on rabbit foliate taste buds and reached antipodal conclusions. Whereas Iwayama concluded that there was a single cell line that differentiated from dark (type I) to intermediate to light (type II) cells, Fujimoto S. and Murray R. (1970) concluded that the different cell types arose from separate cell lines. The same year Sangiacomo C. (1970) described type I, type II, and neurosecretory cells in rabbit foliate taste buds. Today, most investigators have adopted the nomenclature of Farbman A. (1965a) and Murray and co-workers (type I, type II, type III, and type IV) for most mammalian taste buds (see Murray, R., 1973).

4.05.3.1 General Morphological Features of Rabbit Foliate Taste Buds

A longitudinal section through a rabbit foliate taste bud reveals a broad, onion-shaped structure that rests on the basal lamina (Figure 2). The taste bud extends from the basal lamina to the surface of the lingual epithelium (Figure 2). The lamina propria underlying the basal lamina contains connective tissue, vasculature, and nerve processes. Rabbit foliate taste buds range from 30 to 70 μm in width and 50–60 μm in height (Murray, R., 1973; Royer, S. and Kinnamon, J., 1991). The intragemmal taste cells (=cells located within the taste bud proper) display a range of morphologies. Most of the taste cell nuclei are located in the bottom half to two-thirds of the taste bud. Taste cells are joined together at their apices by

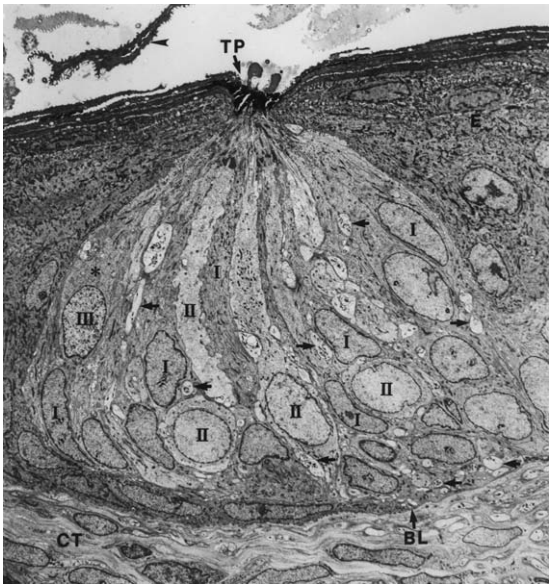

Figure 2 High-voltage electron micrograph (HVEM) of a longitudinal section through a rabbit foliate taste bud. The nucleus and part of the apical process (*) of a type III cell (III) appear at the left margin of this taste bud. Several nuclei and apical processes of type I and II cells are also present. Intragemmal nerve fibers are indicated by arrows. Two plumes of electron-dense pore substance extend above the taste pore (TP). Note the sloughing of the surface layer of the epithelium (E) at the upper left (arrowhead). BL, basal lamina; CT, connective tissue. ×2250. From Royer, S. and Kinnamon J. 1991. HVEM serial-section analysis of rabbit foliate taste buds: I. Type III cells and their synapses. J. Comp. Neurol. 306, 49–72.

tight junctions and by desmosomes elsewhere. Although there is considerable variability in cellular morphology within a taste bud, most taste cells are fusiform to spindle-shaped structures with centrally positioned nuclei. In favorable sections a few taste cells can be seen extending from the base of the taste bud to the taste pit, where apical microvilli from the taste cells project into a cavity below the epithelial surface. The taste pit opens into the oral cavity at the taste pore. The taste pore is typically filled with an electron-dense pore substance. It is not uncommon for foliate taste buds of the rabbit to possess multiple taste pores (Royer, S. and Kinnamon, J., 1991).

Prominent intercellular spaces have been described in taste buds (Nemetschek-Gansler, H. and Ferner, H., 1964; Baradi, A., 1965; Scalzi, H., 1967). Murray R. (1973) noted the high variability of intragemmal intercellular spaces and suggested these spaces were probably artifacts of specimen preparation. Our experience is similar; manipulation of the osmolarity of the fixative can alter the size and shape of intercellular spaces within taste buds. Nerve processes ramify throughout the basal two-thirds of the taste bud. Synapses can be seen from type III cells onto nerve processes (Figure 5). We have used the following criteria to identify synapses (Royer, S. and Kinnamon, J., 1991):

1. a thickening of the presynaptic membrane, with a 15–20 nm cleft separating the parallel membranes;
2. clustering of vesicles adjacent to the membrane thickening; and
3. the appearance of this configuration in at least two consecutive 0.25 μm-thick sections.

When compared with taste cells of rodents, rabbit foliate taste cells are more distinctive and easier to classify into cell types. We have not observed any intermediate or transitional cell types in rabbit foliate taste buds.

4.05.3.2 Primary Foliate Taste Bud Cell Types

4.05.3.2.1 Type I cells

Type I cells (previously termed, dark cells), are slender cells with moderately expanded nuclear regions (Figures 2 and 3). No synaptic connections associated with type I cells have been observed. The type I cell has been referred to as being sustentacular by most investigators, implying that this cell type does not perform a sensory function, although one may wonder about the function of the apical microvilli of these cells. Both basal and apical processes are present, with the apical process terminating in approximately 30–40 long, slender, microvilli varying in length from 1 to 2 μm (Murray, R., 1973). In cross section, the microvilli possess hexagonally arranged electron-dense filamentous material (Scalzi, H., 1967), which is most likely actin. Unlike other cell types, type I cells also possess finger- or sheet-like cytoplasmic processes that separate and envelop type II cells, type III cells, and intragemmal nerve fibers in a Schwann cell-like manner (Murray, R., 1973; Royer, S. and Kinnamon, J., 1994). These processes can best be seen in transverse sections (Figure 3).

The cytoplasmic ground substance of a type I cell varies from intensely electron-dense to electron-lucent. The apical cytoplasm also contains varying amounts of granular and/or smooth endoplasmic reticulum. Perhaps the most distinguishing ultrastructural feature of the type I cell is the presence of numerous

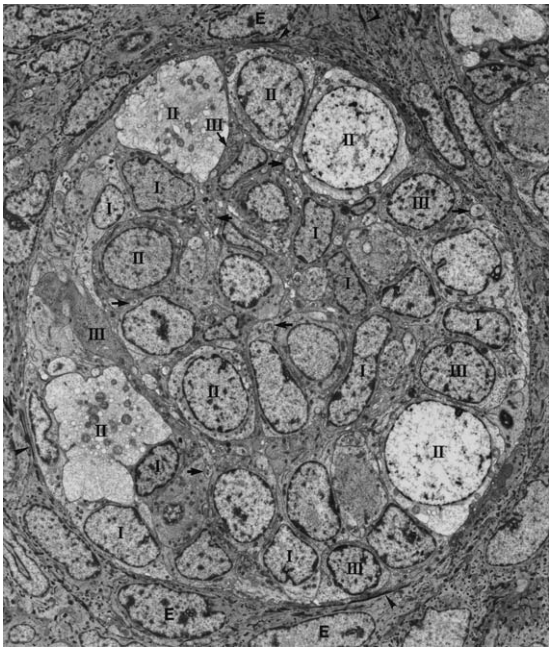

Figure 3 High-voltage electron micrograph (HVEM) of a transverse section through the nuclear region of a rabbit foliate taste bud. Cells of type I, type II, and type III are indicated. Several nerve fiber profiles are labeled with arrows. Note that the nuclei of three of the five type III cells in this taste bud lie along the right edge of the bud. The basal processes of the other two type III cells are located close to the left and top edges, respectively. One of these (at the center left) exhibits densely stained cytoplasm. The taste bud is surround by epithelial cells (E) containing numerous bundles of cytokeratin filaments (arrowheads). ×3900. From Royer, S. and Kinnamon J. 1991. HVEM serial-section analysis of rabbit foliate taste buds: I. Type III cells and their synapses. J. Comp. Neurol. 306, 49–72.

apical, electron-dense granules varying in size from 100 to 400 nm (Murray, R., 1973; Royer, S. and Kinnamon, J., 1994). The similarity of the contents of these granules to the pore substance found in the taste pore suggests that the pore substance is produced by the exocytosis of the apical granules in type I cells (Murray, R. and Murray, A., 1971).

The nuclei of type I cells are irregular in shape but generally are more slender when compared with the round-to-ovoid nuclei of type II cells. The nuclear matrix of a type I cell is considerably more electron-dense than the matrix of a type II or type III cell (Figure 3). Type I cell nuclei are more elongate than type II cell nuclei and contain patchy heterochromatin distributed throughout the nuclear matrix. Clumps of heterochromatin can also be seen adherent to the inner leaflet of the nuclear membrane.

4.05.3.2.2 Type II cells

Type II cells, previously termed, light cells, have a pronounced fusiform appearance, with a noticeably expanded nuclear region (Murray, R., 1973; Royer, S. and Kinnamon, J., 1994) (Figures 2 and 3). At low magnifications, type II cells are distinguished from type I and type III cells by the presence of large, round-to-ovoid nuclei in the type II cells. The nuclear matrix of a type II cell is more uniform in appearance, lacking much of the patchy heterochromatin present in the nuclei of type I cells.

The cytoplasmic ground substance of a type II cell is variable in appearance, but generally more electron-lucent than observed in a type I cell. Type II cells lack the enveloping, sheet-like cytoplasmic processes associated with type I cells, as well as the apical, dense granules characteristic of type I cells. The apical cytoplasm of type II cells often contains swollen or dilated cisternae of smooth endoplasmic reticulum and numerous mitochondria. The apical process of a type II cell terminates in several microvilli of generally uniform length, giving a brush-like appearance. In addition to conventional type II cells, we have observed a subset with large, round, lightly staining nuclei, and extremely electron-lucent, highly vesiculate cytoplasm, which we termed type II-VL (for very light) (Royer, S. and Kinnamon, J., 1994). These cells are primarily found at the periphery of the taste bud (e.g., Figure 3).

4.05.3.2.3 Type III cells

Early descriptions of cell types in rabbit foliate taste buds described only dark and light cells. A third cell type, termed the gustatory receptor, was described by Murray, R. *et al.*, in 1969. Type III cells are spindle-shaped with apical and basal processes and constitute approximately 5% of the cells within a rabbit foliate taste bud (5–15%: Murray, R. *et al.*, 1969; 5–7%: Royer, S. and Kinnamon, J., 1994). The type III cell is the only cell type in foliate taste buds of the rabbit that has been observed to form synaptic connections with nerve processes (Figures 4 and 5). Thus, the type III cell was considered to be the receptor cell (Murray, R., 1973). We found type III cells to be concentrated around the periphery of the taste bud (Figure 3; see also Figure 9: Royer, S. and Kinnamon, J., 1991). This contrasts with Murray's observation that type III cells are centrally placed (Murray, R., 1971). The apical region of the type III cell terminates in a single, blunt microvillus approximately 0.5–0.6 μm in diameter at its base and up to 4–5 μm in length (Royer, S. and Kinnamon, J., 1994). This contrasts

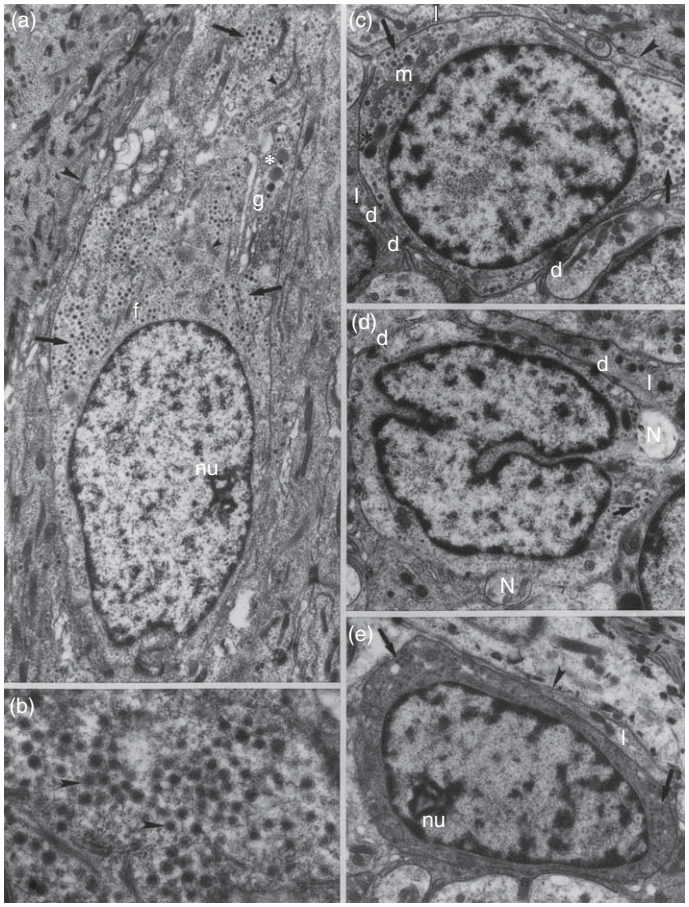

Figure 4 (a) Longitudinal section through the nucleus and apical process of a type III cell (also shown in Figure 2). The cytoplasm of the apical process contains abundant dense-cored vesicles (arrows), Golgi complex (g), lysosome-like dense bodies (*), granular endoplasmic reticulum (small arrowheads), and filaments (f). Nucleolus (nu). The margin of the taste bud indicated by the large arrowhead (cf. Figure 2). ×9600. (b) Higher magnification view of dense-cored vesicles located in the apical process of the type III cell shown in Figures 2 and a. The electron-lucent halo around the dense core is apparent in some of the vesicles (arrowhead). ×28 500. (c) Transverse section through the perikaryal region of a type III cell. A thin type I cell process (l) separates this cell from the border of the taste bud (arrowhead). The cytoplasm of the type III cell contains numerous dense-cored vesicles (arrows), several mitochondria (m), and a dense lysosome-like body (*). Desmosomes (d) attach the type III cell to adjacent type I cells. ×12 700. (d) Transverse section through the parikaryal region of a type III cell. The nuclear membrane displays two deep invaginations. Nerve fibers (N), desmosomes (d). ×11 300. (e) Transverse section through the perikaryal region of a type III cell located at the margin of a taste bud (arrowhead) and separated from surrounding cells by a thin type I cell process. Although the cytoplasm of this cell is quite electron-dense, groups of dense-cored vesicle can still be distinguished (arrows). ×13 100. From Royer, S. and Kinnamon J. 1991. HVEM serial-section analysis of rabbit foliate taste buds: I. Type III cells and their synapses. J. Comp. Neurol. 306, 49–72.

with the multiple microvilli at the apices of both type I and type II cells. In the upper third of the taste bud, type III cells are often separated from other cells by the cytoplasmic processes of type I cells, but may contact each other in the basal region. As with other taste cells, type III cells are joined to adjacent cells by desmosomes. Radiating from the desmosomes are numerous intermediate filaments that project into the cytoplasm.

The cytoplasm of a type III cell is variable, but usually moderately electron-dense (Royer, S. and Kinnamon, J., 1994). Scattered throughout the cytoplasm are mitochondria, granular and smooth endoplasmic reticulum, free ribosomes, and polyribosomes. The cytoplasmic ground substance of a small subset of type III cells is significantly more electron-dense (e.g., Figures 3 and 4). These cells have been termed dark type III cells (Murray R.,

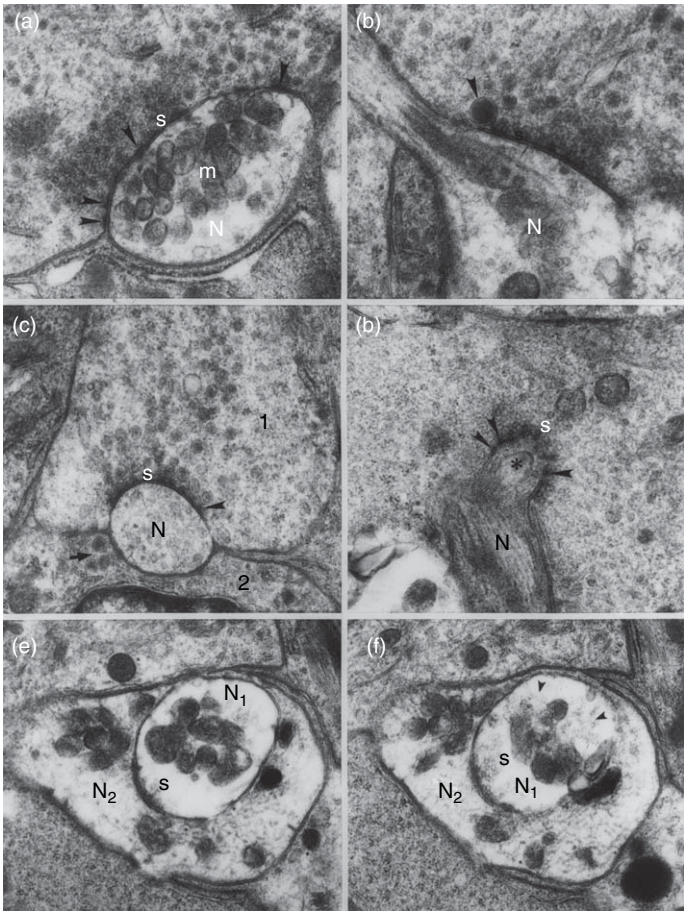

Figure 5 (a) Synapse (s) between a type III cell and a nerve process (N). Note the dense cloud of small, clear-cored vesicles as well as several large, dense-cored vesicles at the presynaptic site and presynaptic dense projections (arrowheads). The nerve fiber contains numerous mitochondria (m). ×36 900. (b) Synapse (s) from a type III cell onto an enlarged nerve process (N). Note the synaptic cleft and the very large dense-cored vesicle (arrowhead) adjacent to the synapse. ×44 600. (c) A small nerve fiber (N) lying between two adjacent type III cells (1 and 2) is postsynaptic to one of these cells (cell 1). Numerous dense-cored vesicles and presynaptic dense projections (arrowhead) are evident. The arrow points to a small group of dense-cored vesicles in cell 2 near its contact with the nerve fiber. ×29 900. (d) Synapse (s) from a type III cell onto a finger-like projection (*) of a nerve fiber (N). Presynaptic dense projections are indicated by arrowheads. ×37 900. (e, f) An axoaxonal synapse (s) between two nerve fibers. N_1 is presynaptic to N_2 and contains a cluster of clear vesicles adjacent to the presynaptic membrane. Dense material adheres to the postsynaptic membrane in N_2. Arrowheads in F indicate groups of clear vesicles in N_1. (e) ×32 600. (f) ×29 000. From Royer, S. and Kinnamon J. 1991. HVEM serial-section analysis of rabbit foliate taste buds: I. Type III cells and their synapses. J. Comp. Neurol. 306, 49–72.

and Murray, A., 1971). Murray R. (1986) speculated that dark type III cells might be developing or degenerating type III cells. A distinguishing feature of the type III cell is the presence of large, dense-cored vesicles (80–140 nm) with prominent electron-lucent halos (Figure 4). These vesicles are especially numerous in the cytoplasm surrounding the nucleus. These vesicles are distributed throughout the cytoplasm and should not be confused with the small, clear vesicles (40–60 nm) located at the presynaptic regions (see below).

The nuclei of type III cells are situated in the lower half of the taste bud. These nuclei are intermediate in appearance between the nuclei of type I and type II cells (Figures 2 and 3). Type III cell nuclei are ovoid to round in cross section, similar to type II cell nuclei, but elongate in longitudinal section like type I cell nuclei. The density of the nuclear matrix of a type III cell is intermediate between that of a type I and a type II cell. Like type I cells, the nuclei of type III cells possess prominent nuclear invaginations (Figures 3 and 4). Another similarity

between the nuclei of type III cells and type I cells is the presence of clumps of heterochromatin scattered throughout the nuclear matrix, some of which are adherent to the nuclear membrane.

4.05.3.2.4 Synaptic connections

Type III cells are the only cells that have been observed to form synapses with intragemmal nerve fibers (Murray, R. and Murray, A., 1970; 1971; Murray, R., 1971; 1973; Royer, S. and Kinnamon, J., 1991; 1994). It is curious that both type I and type II cells possess apical microvilli – putative sites for sensory transduction – yet neither cell type forms conventional chemical synapses with nerve processes. We found that some type III cells had divergent synaptic connections with synapses from a single type III cell onto a maximum of six nerve processes. Convergence of input from two to three type III cells onto a single nerve process was also a common observation. Most synapses are located on the basolateral region of the type III cell. These synapses are usually asymmetrical with electron-dense presynaptic thickenings, often including presynaptic dense projections (Figure 5). Type III cell synapses in rabbit foliate taste buds are especially well developed when compared with synapses in taste buds of rodents. Round, clear vesicles (40–60 nm) of varying numbers are associated with the presynaptic active zone (Royer, S. and Kinnamon, J., 1991; 1994). Dense-cored vesicles can also be present at these synapses. In some instances, only a few dense-cored vesicles are interspersed among the clear vesicles. At other synapses dense-cored vesicles are the predominant vesicle type. Thus, there may be more than one type of synapse associated with type III cells, as well as more than one neurotransmitter/neuromodulator. On rare occasions we have observed neuroneuronal synapses in taste buds (e.g., Figures 5(e) and 5(f)).

4.05.4 Rodent Taste Buds

4.05.4.1 Innervation

Lingual taste buds in rodents are innervated by branches of the facial (VII cranial) and glossopharyngeal (IX cranial) nerves (Whiteside, B., 1927; Oakley, B., 1967; Beidler, L., 1969; Farbman, A. and Hellekant, G., 1978; Bradley, R. 1971; Whitehead, M. *et al*., 1985) (Figure 1). Fungiform and anterior foliate taste buds of rodents are innervated by the chorda tympani branch of the VII cranial nerve. This differs from innervation of rabbit foliate taste buds, which are innervated only by the glossopharyngeal (IX) nerve. Taste buds in the vallate and posterior foliate papillae of rodents are innervated by the fibers of the lingual–tonsillar branch of the glossopharyngeal cranial nerve (IX) (Whiteside, B., 1927; Oakley, B., 1967).

4.05.4.2 General Morphological Features

Recent evidence indicates that taste cells in rodents are epithelial in origin (Stone, L. and Finger, T., 1994; Stone, L. *et al*., 1995). The classic study on taste cell turnover in the rat was carried out by Beidler L. and Smallman R. (1965), who found that taste cells were replaced approximately every 10 days to 2 weeks. Rodent taste buds are onion-shaped structures with spindle-shaped cells that span the entire length of the taste bud from the basal lamina up to the taste pore. Taste cell nuclei are usually located in the lower third of the taste bud. Based on their staining characteristics and ultrastructural features, taste cells are currently classified into type I (dark), II (light), type III, and type IV (basal) cells. The type I, type II, and type III cells extend their microvilli into the taste pore (Figure 7). The structural features of the microvilli are distinctive for each of the taste cell types (Figure 7). Electron-dense pore substance is present in the taste pore, although its function is unclear. Basal cells are found near the base of the bud, but these cells lack apical processes. Nerve fibers are abundant in the connective tissue underlying the taste buds and penetrate the taste bud at its base and course throughout the bud. Most nerve fibers terminate in the lower half of the taste bud, where they may receive synaptic contacts from taste cells.

4.05.4.3 Primary Taste Bud Cell Types

Farbman A. (1965a) introduced the nomenclature type I and type II taste cells and classified taste cells in rat taste buds into four types: peripheral, basal (type IV), type I (dark), and type II (light) cells (Figure 8). The type III cell was first described in the rat by Takeda M. and Hoshino T. (1975) and in circumvallate taste buds of the mouse by Takeda M. (1976). Type III cells were considered to be sensory cells because they were the only cell type forming synaptic contacts onto nerve processes in rodent taste buds (Takeda, M. and Hoshino, T., 1975; Takeda, M., 1976). Using ultrastructural criteria, we classified taste cells in mouse circumvallate taste buds into

dark cells (type I), intermediate cells, light cells (type II), basal cells, and undifferentiated peripheral cells (Scalzi, H. 1967; Iwayama, T., 1970; Kinnamon, J. *et al.*, 1985; Delay, R. *et al.*, 1986; Kinnamon, J. *et al.*, 1988). Dark cells, intermediate cells, and light cells all appeared to form synaptic contacts with nerve processes (Kinnamon, J. *et al.*, 1985; 1988). Recent studies using immunofluorescence and immunoelectron microscopy with antisera markers for different taste cell types indicate that cells originally classified as intermediate cells in mouse circumvallate taste buds should properly be classified as type III cells (Yang, R. *et al.*, 2000a; Yee, C. *et al.*, 2001; Clapp, T. *et al.*, 2004; Yang, R. *et al.*, 2004). Thus, type III cells in rat circumvallate taste buds are believed to be the only cell type that forms classical synapses onto nerve processes (Yang, R. *et al.*, 2000b; Yee, C. *et al.*, 2001; Yang, R. *et al.*, 2004). Type II cells do not form classical synapses with nerve fibers. Instead, at the points of contact with nerve fibers, type II cells exhibit SSCs of smooth endoplasmic reticulum (Royer, S. and Kinnamon, J., 1988; Clapp, T. *et al.*, 2004), that suggest a functional contact with nerve processes.

4.05.4.3.1 Type I cells

Farbman A. (1965a) built upon the dark cell and light cell nomenclature of Murray and coworkers, referring to dark cells as type I cells and light cells as type II cells. Type I cells (Figures 6 and 8), are the most numerous taste cells (50–60%), usually located peripherally in the taste bud (Farbman, A. 1965a; Murray, R., 1973; Kinnamon, J. *et al.*, 1985; Delay, R. *et al.*, 1986). These cells are slender with electron-dense cytoplasm and elongate, electron-dense nuclei with, prominent, distinguishing nuclear invaginations. These cells span the entire length of the taste bud from the basal lamina to the taste pore (Figure 6). The apical end of a type I cell terminates in several long and slender microvilli (Figure 7). Perhaps the most distinguishing feature of type I cells involves the numerous dense-cored granules (100–400 nm in diameter) located in the apical cytoplasm (Figures 7 and 8). These dense-cored granules, which are conspicuously absent in type II cells, are present in the apical cytoplasm of type I cells in both mouse and rat foliate and circumvallate taste buds. This is not the case, however, with fungiform taste buds. Several investigators have reported that the apical cytoplasm of type I cells in fungiform taste buds lacks the dense-cored granules (Farbman, A. 1965a; Murray, R., 1973; Kinnamon, J. *et al.*, 1988; Royer, S. and Kinnamon, J., 1991; Kinnamon, J. *et al.*, 1993; Reutter, K. and Witt, M., 1993; Miller, I., 1995). Other investigators have observed dense-cored granules in the type I cells of rat fungiform taste buds, but those granules were rod-shaped, only moderately electron-dense, and few in number. This contrasts with the circular, electron-dense apical vesicles observed in type I cells of circumvallate taste buds (Takeda, M. and Hoshino, T., 1975). These apical granules are believed to be secretory precursors of the dense substance in the taste pore (Murray, R. and Murray, A., 1967; Scalzi, H., 1967). The function of the dense pore substance is unknown, however, it may play an important role in facilitating and modifying the response of taste receptor cells to sapid stimuli (Murray, R. and Murray, A., 1970). Type I cells have irregular cytoplasmic processes that surround type II or type III taste cells. Thus, type I cells may function like

Figure 6 Longitudinal section through a taste bud from a rat circumvallate papilla. A type I cell (I) or dark cell contains electron-dense cytoplasm and a slender nucleus. Dense-cored granules (arrows) are present in the apical cytoplasm. A type II (II) or light cell has a large, circular nucleus and an electron-lucent cytoplasm. Taste pore (TP); nerve process (arrow); epithelium (E). ×4500. Adapted from Yang, R., Crowley, H., Rock, M. and Kinnamon, J. 2000a. Taste cells with synapses in rat circumvallate papillae display SNAP-25-like immunoreactivity. J. Comp. Neurol. 424, 205–215.

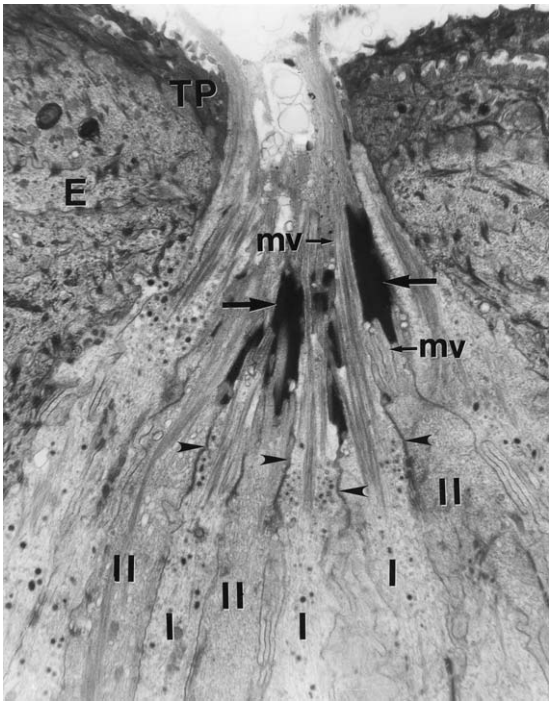

Figure 7 Longitudinal section through the taste pore region from a rat circumvallate taste bud. type I cells (I) are characterized by the presence of apical dense-cored granules (arrowheads) and several long, slender microvilli, whereas the apical microvilli of the type II cells (II) are brush-like, i.e., short and uniform in length. The most distinguishing ultrastructural feature of the type III cell (III) is the presence of a single, large, blunt microvillus that extends onto taste pore. The taste cells are joined by tight junctions (arrowheads). Microvilli (MV); pore substance (arrows); taste pore (TP); nongustatory epithelium (E). ×21 000.

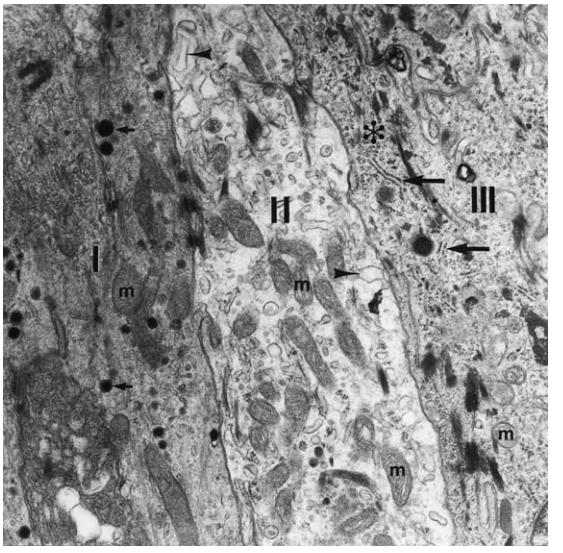

Figure 8 Longitudinal section showing the apical cytoplasm of three taste cells (I, II, and III) from a mouse taste bud. The electron-dense cytoplasm of the type I cell (I) contains numerous dense-cored granules (small arrows). The cytoplasm of the type I cell is rich in filaments and contains mitochondria and free ribosomes. The cytoplasm of the type II cell (II) is electron-lucent with numerous mitochondria (m) and swollen cisternae of agranular endoplasmic reticulum (arrowheads). Type III cells (III) exhibit electron density intermediate between that of type I (I) and type II (II) cells. The cytoplasm of type III cells contains numerous free ribosomes and rough endoplasmic reticulum. ×35 000.

glial cells in terms of isolation and nutrition (Reutter, K. and Witt, M., 1993; Pumplin, D. *et al.*, 1997). Although type I cells possess apical microvilli and are in direct contact with nerve processes, no synaptic contacts are believed to be present between type I cells and nerve processes (Farbman, A., 1965a; Murray, R., 1973; Reutter, K. and Witt, M., 1993). Although early studies suggested that type I cells might function as sensory receptors, it is generally accepted that they are restricted to a supportive or sustentacular role (Murray, R. and Murray, A., 1971; Murray, R., 1986; Lindemann, B., 1996; Lawton, D. *et al.*, 2000; Bartel, D. *et al.*, 2006).

The dark appearance of type I cell cytoplasm (Figure 8) results from an electron-dense ground substance, close packing of free ribosomes and polyribosomes, scattered cisternae of rough endoplasmic reticulum, and bundles of filamentous material surrounding the nucleus. The cytoplasm of type I cells also contains numerous mitochondria with densely staining matrices and lamellar cristae. These mitochondria are rod-shaped or elongate and randomly distributed throughout the cytoplasm. The Golgi bodies of type I cells typically consist of stacks of flattened cisternae, which are expanded only at their edges (Kinnamon, J. *et al.*, 1988).

The nuclei of type I cells are variable in profile. Compared with type II taste cells, the nuclei of type I cells are small, irregular, and electron-dense (Figure 6) (Kinnamon, J. *et al.*, 1985). The nuclei often contain one or more poorly defined nucleoli or aggregations of heterochromatin adhering to the inner leaflet of nuclear membrane (Kinnamon, J. *et al.*, 1988). The invaginations of type I cell nuclei are smaller than the deep prominent invaginations of type III cell nuclei.

4.05.4.3.2 Type II cells

The type II cell, initially termed light cell, constitutes approximately 15–30% of the cells in a taste bud

(Farbman, A., 1965a; Murray, R., 1973; Kinnamon, J. *et al.*, 1985; Delay, R. *et al.*, 1986) (Figures 6 and 8). Most type II cells extend the entire length of the taste bud from the basal lamina to the taste pore. A small subset of these cells, however, are located in the upper third of the taste bud and possess no apparent basal processes. These cells have a triangular profile in longitudinal sections. A typical type II cell possesses an electron-lucent cytoplasm and large circular or ovoid nuclei (Farbman, A., 1965a; Murray, R., 1973; Kinnamon, J. *et al.*, 1985; Delay, R. *et al.*, 1986; Kinnamon, J. *et al.*, 1988; Royer, S. and Kinnamon, J., 1988; Royer, S. and Kinnamon, J., 1991; Kinnamon, J. *et al.*, 1993; Royer, S. and Kinnamon, J., 1994; Pumplin, D. *et al.*, 1997). In contrast with the type I cell, the apical portion of a type II cell is wider than the type I cell and lacks the apical dense granules characteristic of the type I cells. The apical microvilli of a type II cell are numerous, short, and uniform in length, giving a brush-like appearance (Figure 7). Type II cells lack classical chemical synapses with nerve processes (Farbman, A., 1965a; Murray, R., 1973; Yee, C. *et al.*, 2001; Yang, R. *et al.*, 2004). However, other type II cell–nerve process contacts, such as SSCs of smooth endoplasmic reticulum and atypical mitochondria have been found at close appositions between taste cells and nerve processes (Farbman, A. 1965a; Fujimoto, S. and Murray, R., 1970; Murray, R., 1971; Takeda, M., 1976; Ide, C. and Munger, B., 1980; Royer, S. and. Kinnamon, J., 1988). Results from our laboratory suggest that SSCs are found exclusively at close appositions between type II cells and nerve processes in rat circumvallate taste buds (Clapp, T. *et al.*, 2004).

The cytoplasm of a type II cell contains an abundance of mitochondria, vesicles, and vacuoles (Farbman, A., 1965a) (Figure 6). The supranuclear region of a type II cell is rich in microchrondia, and more apically, the cytoplasm is replete with swollen vesicles of agranular endoplasmic reticulum. The cytoplasm also contains rough endoplasmic reticulum, free ribosmes, and intermediate filaments.

The nuclei of type II cells are large with a round-to-ovoid profiles. These nuclei are generally electron-lucent with a homogeneous nuclear matrix containing one to a few nucleoli (Kinnamon, J. *et al.*, 1985; Delay, R. *et al.*, 1986; Kinnamon, J. *et al.*, 1988; Reutter, K. and Witt, M., 1993) (Figure 6). In contrast with type I cell nuclei, the nuclei of type II cells generally lack invaginations and have fewer aggregations of heterochromatin and electron-dense material.

4.05.4.3.3 Type III cells

Type III cells (Figure 8) were first described in the foliate papillae of rabbits (Murray, R., 1973), but this cell type is present in other species as well, including the mouse (Takeda, M., 1976; 1977; Takeda, M. and Kitao, K., 1980; Takeda, M. *et al.*, 1981), rat (Takeda, M. and Hoshino, T., 1975; Yee, C. *et al.*, 2001; Yang, R. *et al.*, 2004), monkey (Farbman, A. *et al.*, 1985), and guinea-pig (Yoshie, S. *et al.*, 1990). Type III cells represent of the smallest proportion (5–15%) of taste cells in taste buds (Delay, R. *et al.*, 1986; Reutter, K. and Witt, M., 1993; Kinnamon, 1997). Type III cells are slender cells with a moderately electron-lucent cytoplasm. These cells span the entire length of taste buds from basal lamina to taste pore with a cytoplasm containing numerous ribosomes and cisternae of granular endoplasmic reticulum (Takeda, M. and Hoshino, T., 1975; Kinnamon, J. *et al.*, 1985; 1988; Reutter, K. and Witt, M., 1993; Kinnamon, J. 1987). The nuclei are intermediate in appearance between the nuclei of type I and type II cells (Takeda, M. and Hoshino, T., 1975; Yang, R. *et al.*, 2004; 2007). Type III cells in the mouse and rat taste buds lack the large dense-cored vesicles seen in the nuclear region of the cytoplasm of type III cells in rabbit foliate taste buds. The primary distinguishing features of type III cells in mouse and rat taste buds are as follows:

1. an elongate nucleus with large prominent invaginations;
2. a single, large, blunt microvillus that extends into the taste pore;
3. synapses onto nerve processes (Takeda, M. and Hoshino, T., 1975; Takeda, M., 1976; Royer, S. and Kinnamon, J., 1991); and
4. dense-cored vesicles (90–120 nm in diameter) and numerous clear vesicles (40–70 nm in diameter) are present at presynaptic sites (Kinnamon J. *et al.*, 1985; 1988; Yang, R. *et al.*, 2000a; 2004; 2007) (Figures 7, 9, and 10).

4.05.4.3.4 Type IV cells (basal cells)

Type IV cells lie in the basolateral region of taste buds. These cells are small, irregular, and similar to peripheral cells in morphology. but do not exend apical processes to the taste pore (Farbman, A., 1965a; 1965b; Reutter, K. and Witt, M., 1993). The most distinguishing feature of basal cells is the presence of intermediate filaments attached to the nuclear envelope (Delay, R. *et al.*, 1986). These cells

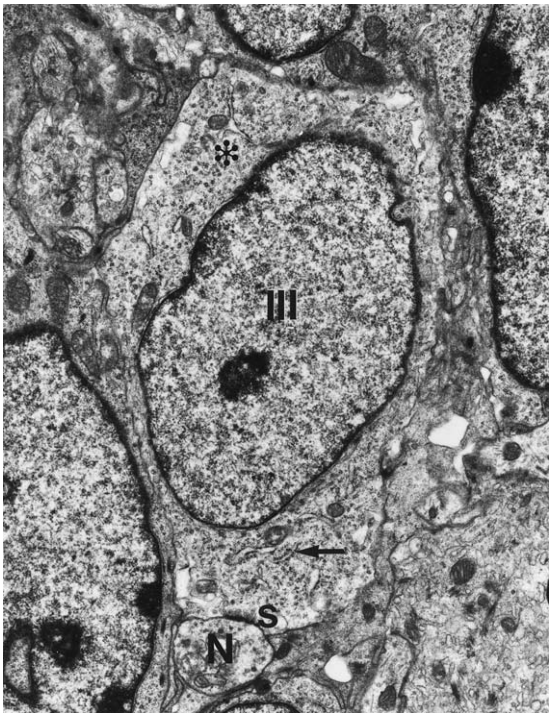

Figure 9 A low-magnification micrograph showing a mouse circumvallate type III taste cell (III) with a synapse (S) onto a nerve process. The cytoplasm of the taste cell contains numerous polyribosomes ribosomes (asterisk) and rough endoplasmic reticulum (arrow). The nucleus contains a small invagination and a prominent nucleolus. A group of small, clear synaptic vesicles are aggregated at the active zone of the synapse. The postsynaptic element, a nerve process (N) contains several mitochondria. ×15 000. Adapted from Kinnamon, J., Taylor, B., Delay, R. and Roper, S. 1985. Ultrastructure of mouse vallate taste buds. I. Taste cells and their associated synapses. J. Comp. Neurol. 235, 48–60.

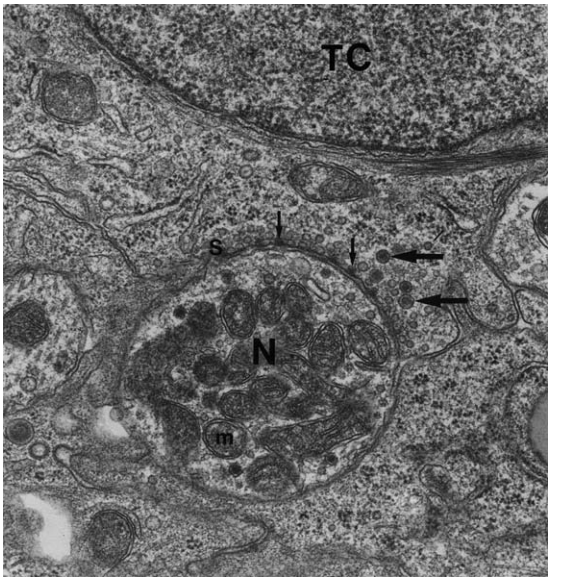

Figure 10 High magnification micrograph showing a macular synapse (S) from a mouse circumvallate taste cell (TC) onto a nerve process (N). Several small clear synaptic vesicles (40–70 nm) and a few large dense-cored vesicles (90–120 nm) (large arrows) are present at the presynaptic zone. Presynaptic dense projections (small arrows) can be seen at the synapse. The nerve process is replete with mitochondria (m), dense-cored vesicles and small clear vesicles. ×38 000. Adapted from Kinnamon, J., Sherman, T. and Roper, S. 1988. Ultrastructure of mouse vallate taste buds: III. Patterns of synaptic connectivity. J. Comp. Neurol. 270, 48–60.

are considered to be the precursor cells for other taste cell types in taste buds (Beidler, L. and Smallman, R., 1965; Conger, A. and Wells, M., 1969, Farbman, A., 1980, Stone *et al.*, 2002).

4.05.4.4 Taste Cell Synapses

De Lorenzo A. (1960) suggested that nerve fibers are in continual state of flux, forming synapses with new taste cells and retracting synapses from dying taste cells. Ultrastructural correlates of synapses in taste buds were first observed five decades ago (De Lorenzo, A. 1960; 1963; Gray, E. and Watkins, K., 1965; Hirata, Y., 1966), although Trujillo-Cenóz (1961) described contacts between taste cells and nerve fibers in catfish barbels. The presence or absence of synapses often has been used as a criterion for sensory function in taste cells (Hirata, Y., 1966; Uga, S. and Hama, K., 1967; Murray, R., 1969; 1973; Takeda, M. and Hoshino, T., 1975; Takeda, M., 1976; Ide, C. and Munger, B., 1980; Zahm, D. and Munger, B., 1983a; 1983b; Kinnamon, J. *et al.*, 1985; 1988; 1993). Most investigators now consider the type III cell to be the chemoreceptor cell. In the mouse approximately 20% of the taste cells have synapses onto nerve processes in circumvallate taste buds (Kinnamon, J. *et al.*, 1985). Synapses in fungiform taste buds are fewer, but contain more vesicles than synapses in either circumvallate or foliate taste buds (Kinnamon, J. *et al.*, 1993). Virtually, all synapses in mammalian taste buds are from taste cells onto nerve fibers (Murray, R. and Murray, A., 1967; Scalzi, H., 1967; Beidler, L., 1969; Murray, R., 1969; Takeda, M. and Hoshino, T., 1975; Takeda, M., 1976; Miller, R. and Chaudhry, A., 1976; Takeda, M. *et al.*, 1981; Kinnamon, J. *et al.*, 1985; 1988; Royer, S. and Kinnamon, J., 1988; Kinnamon, J. *et al.*, 1993; Yang, R. *et al.*, 2000a; Yee, C. *et al.*, 2001; Yang, R. *et al.*, 2004). Taste cell synapses are generally located near the

nuclear region of the presynaptic taste cell (Figure 9). The synaptic structure varies from macular to finger-like (Kinnamon, J. *et al.*, 1985; Yang, R. *et al.*, 2000a; 2004). The macular synapses are punctate and usually flat (Figure 10). A typical finger-like synapse, however, consists of a process from a postsynaptic nerve fiber protruding into an invagination of the presynaptic taste cell (Kinnamon, J. *et al.*, 1985). Synapses between intragemmal nerve processes are commonly observed during taste bud development (Kinnamon, J. *et al.*, 2005), but only rarely in taste buds of adult animals (however, see Graziadei, P. 1969; Royer, S. and Kinnamon, J., 1988; 1994). The function of neuroneuronal synapses in taste buds is not well understood.

4.05.4.5 Putative Nonsynaptic Connections

It is generally accepted that type II cells are important in the transduction of bitter, sweet, and umami taste, yet these cells do not form synapses onto nerve fibers. Other specialized contacts between taste cells and nerve processes have been observed that may be part of the transduction pathway, including SSCs of smooth endoplasmic reticulum and atypical mitochondria (Figures 11–13).

4.05.4.5.1 Subsurface cisternae of smooth endoplasmic reticulum

SSCs are narrow sacs of agranular endoplasmic reticulum that lie adjacent to the cytoplasmic leaflet of taste cell membranes at sites of close apposition with nerve processes (Figure 11) (Royer, S. and Kinnamon, J., 1988). The outer membranes of the cisternae are separated from the inner leaflet of the taste cell membrane by a narrow gap averaging 15 nm in width. The close apposition between the cisternae and cell membrane may extend for a distance up to 2–3 μm (Figure 11). SSCs have been reported in rat fungiform taste buds (Farbman, A., 1965a), rabbit foliate taste buds (Fujimoto, S. and Murray, R., 1970; Murray, R., 1971), mouse vallate and foliate (Takeda, M., 1976; Royer, S. and Kinnamon, J., 1988), and monkey laryngeal taste buds (Ide, C. and Munger, B., 1980). SSCs have been found at the close appositions between the plasma membrane of type II taste cells and nerve processes (Clapp, T. *et al.*, 2004). Although the function of SSCs is unclear, we speculate that the type II cells may communicate to the nerve processes via SSCs (Romanov, R. *et al.*, 2007).

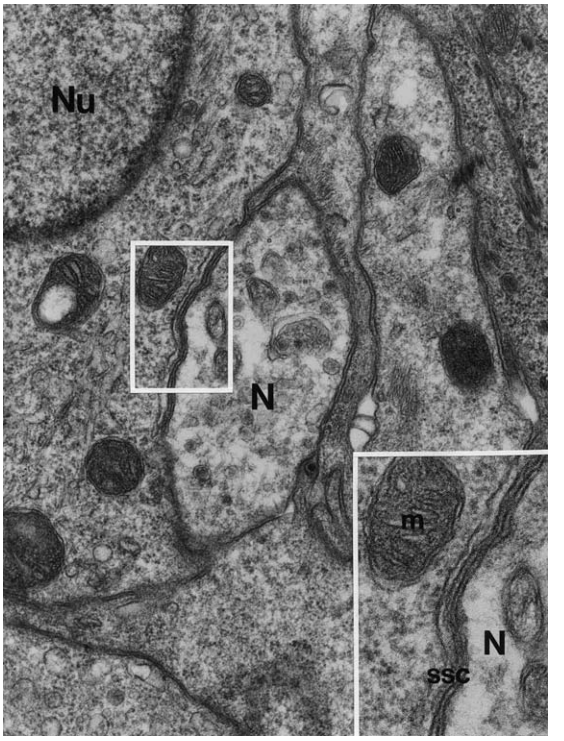

Figure 11 Electron micrograph showing a subsurface cisterna in close apposition to the junction of a taste cell (TC) with a nerve process (N). ×40 000. Inset: High magnification of the subsurface cisterna as it abuts the taste cell membrane. ×90 000. Adapted from Royer, S. and Kinnamon, J. 1988. Ultrastructure of mouse foliate taste buds: synaptic and nonsynaptic interactions between taste cells and nerve fibers. J. Comp. Neurol. 270, 11–24.

4.05.4.5.2 Atypical mitochondria

Most mitochondria in taste cells are elongate, slender structures with lamellar cristae rarely exceeding 0.3 μm in diameter (Royer, S. and Kinnamon, J., 1988) (Figure 12). At sites of close apposition between taste cells and nerve fibers, we occasionally observe unusually large, atypical microchondria (Figure 12). These atypical mitochondria are found only at the close appositions with nerve processes. The atypical mitochondria that we have observed have diameters two to three times larger and do not possess the lamellar or baffle cristae of conventional mitochondria. The cristae of the atypical mitochondria exhibit a twisted-energized or swollen twisted-energized configuration (Figure 12) (Korman, E. *et al.*, 1970; Williams, C. *et al.* 1970), presenting the impression of electron-dense sacs or tubules within the mitochondrion. The outer membranes of the mitochondria are separated from the taste cell membrane by a gap of approximately 20 nm. In favorable

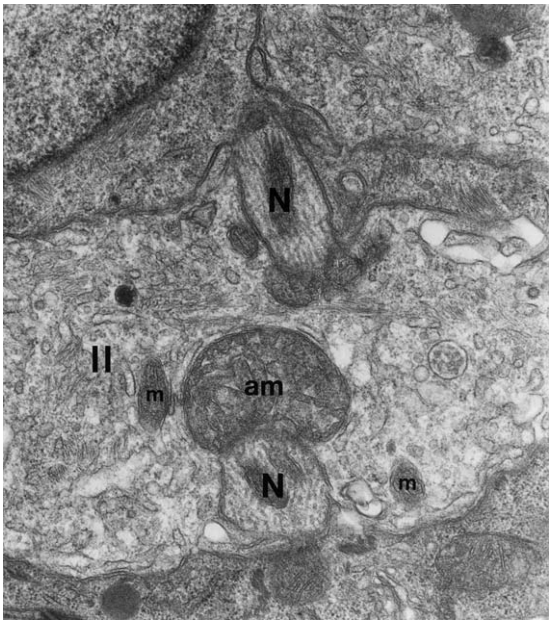

Figure 12 An atypical mitochondrion (AM) between a type II cell (II) and two nerve processes (N). The AM has a diameter two to three times larger than conventional mitochondria. The cristae of the atypical mitochondria exhibit a twisted-energized or swollen twisted-energized configuration. ×30 000. Adapted from Royer, S. and Kinnamon, J. 1988. Ultrastructure of mouse foliate taste buds: synaptic and nonsynaptic interactions between taste cells and nerve fibers. J. Comp. Neurol. 270, 11–24.

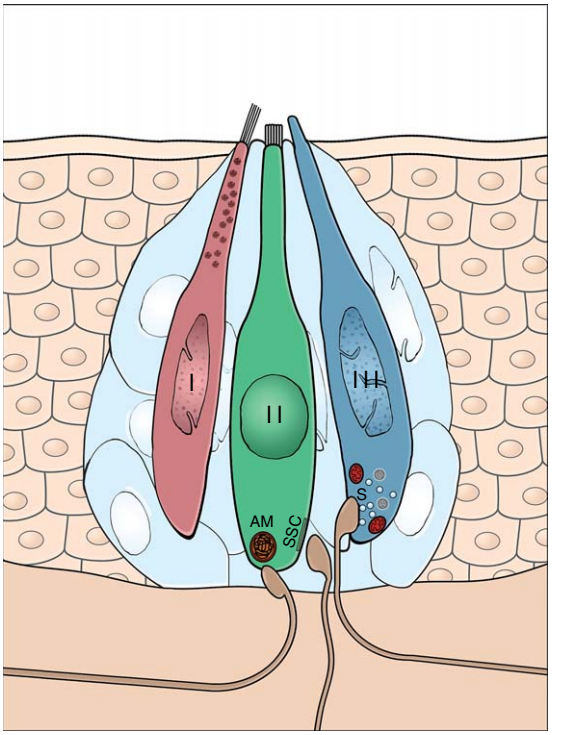

Figure 13 Diagram of a rat circumvallate taste bud showing a type I cell (I), a type II cell (II), and a type III cell (III). The type I cell has an electron-dense cytoplasm and a slender, elongate nucleus with invaginations and clumpy heterochromatin. The apical region of the type I cell contains dense granules and several long, slender microvilli. The type II cell is spindle-shaped with an electron-lucent cytoplasm. The nucleus of a type II cell is round to ovoid with a homogeneous nuclear matrix containing little heterochromatin. Subsurface cisternae (SSC) of smooth endoplasmic reticulum or atypical mitochondria (AM) are sometimes present at junctions with nerve processes. The apical cytoplasm of a type I cell often contains swollen cisternae of smooth endoplasmic reticulum. Several short, apical microvilli of uniform length give a brush-like appearance. The type III cell is slender with cytoplasm that is intermediate in electron density between a type I and type II cell. The slender nucleus contains patchy heterochromatin and pronounced invaginations. A single large, blunt, apical microvillus extends into the taste pore. Type III cells form synapses onto nerve processes. The presynaptic region of the type III cell contains numerous small, clear vesicles and a few large, dense-cored vesicles.

profiles, an electron-dense, wispy material can be seen connecting the mitochondrion to the inner leaflet of the taste cell plasma membrane. Because of their large size, the atypical mitochondria at taste cell–nerve fiber contacts would seem to be significant energy reservoirs and as such would be ready sources of ATP (Royer, S. and Kinnamon, J., 1988; Romanov, R. *et al.*, 2007). This is supported by recent results which demonstrate the importance of ATP as a neurotransmitter in taste buds (Finger, T., 2005).

4.05.5 Concluding Remarks

There is general agreement concerning the ultrastructure of circumvallate taste buds of rodents (Figure 13). The three most significant cell types are type I, type II, and type III cells. Features of type I (dark) cells: (1) slender cells with electron-dense cytoplasm, (2) elongate, electron-dense nuclei with prominent invaginations, (3) dense granules in the apical cytoplasm, and (4) several, long, slender microvilli projecting into the taste pore. Type I (dark) cells are believed to perform a glial function and to isolate other taste cells, but are not thought to be receptor cells. Features of type II (light) cells: (1) these cells are spindle-shaped with an expanded nuclear region and an electron-lucent cytoplasm, (2) type II cell have round-to-ovoid nuclei with a homogeneous, electron-lucent nuclear matrix,

(3) there are several short, apical microvilli of the same length, giving a brush-like appearance, and (4) recent electrophysiological and molecular biological studies indicate that type II cells are chemoreceptors. Although type II cells lack classical chemical synapses, they do possess specialized junctions with nerve processes involving SSCs of smooth endoplasmic reticulum or large, atypical mitochondria. Features of type III cells: (1) type III cells are slender and possess a moderately electron-lucent cytoplasm, (2) the nuclei are slender and contain prominent nuclear invaginations, (3) there is a single, blunt apical microvillus, and (4) type III cells have classical chemical synapses onto nerve processes with small, clear vesicles and large, dense-cored vesicles.

Our understanding of taste bud structure and function has increased greatly over the past 20 years. Knowledge of the ultrastructural features of a taste bud helps to understand the structural basis for taste function, but is not an explanation of taste cell function. Previously, investigators have made well-meaning attempts to infer taste cell function based solely on structural features. Several new approaches now make it possible to elucidate the function of taste cells and correlate this information with the structural features of taste cells. Immunohistochemistry and immunoelectron microscopy using markers for taste cells types and transduction pathways have provided significant indirect data that have enhanced our understanding of taste cell function. The use of the patch clamp recording technique has made it possible to characterize the electrophysiological properties of individual taste cells. Molecular and genetic approaches have made it possible to learn more about taste cell function by using transgenic and knockout mice. Recent studies have led to the identification of two families of G protein-coupled receptors (GPCRs) in taste cells: the T1Rs (T1R1, T1R2, and T1R3) (Hoon, M. *et al*., 1999; Nelson, G. *et al*., 2001; Sainz, E. *et al*., 2001) and T2Rs (Adler, E. *et al*., 2000). T1R1 is primarily expressed in the receptor cells of fungiform taste buds, and T1R2 is expressed in the receptor cells of circumvallate and foliate taste buds. T1R3, however, is broadly expressed in all lingual taste buds (Hoon, M. *et al*., 1999; Sainz, E. *et al*., 2001). T1R1 and T1R2 are expressed in separate taste cells and localize in the taste pore where the microvilli of the taste receptor cells exposed to taste stimuli. T1R1 and T1R3 are believed to function in the transduction of amino acid (umami) stimuli (Nelson, G. *et al*., 2002; Li, X. *et al*., 2002), whereas T1R2 and T1R3 transduce sweet stimuli (Nelson, G. *et al*., 2001; Li, X. *et al*., 2002). The three T1Rs taste receptors are rarely coexpressed with α-gustducin in taste cells in circumvallate and foliate taste buds (Kim, M. *et al*., 2003; Stone, L. *et al*., 2007). T2Rs are exclusively expressed in taste receptor cells that contain gustducin, a G protein α subunit, implying that T2Rs are associated with bitter transduction (Adler, E. *et al*., 2000; Chandrashekar, J. *et al*., 2000; Matsunami, H. *et al*., 2000). T1Rs and T2Rs are almost completely coexpress with TRMP5 and PLCβ2. Sweet, amino acid, and bitter reception are abolished inPLCβ2 knockout mice (Zhang, Y. *et al*., 2003). T1Rs and T2Rs are believed to present in different subsets of type II taste cells. Most or all T2Rs are expressed in a particular subset of taste receptor cells that do not express T1Rs (Chandrashekar, J. *et al*., 2000). Using combinations of the techniques described above it is now possible to truly begin to correlate structure with function in the taste cell and taste bud.

4.06.1 Introduction

At birth, all vertebrates possess a functional taste system. This sensory system is key for young animals to survive in a new world, in which they must avoid noxious and potentially lethal substances, yet ingest nutritionally valuable foods. From a developmental biologist's perspective, the taste system comprises four basic elements which arise in locations remote from one another and must connect accurately during embryogenesis. Specifically these components are: (1) taste buds arrayed within the mouth and pharynx; (2) sensory neurons residing within the cranial nerve ganglia which connect taste buds to (3) discrete gustatory regions of the hindbrain, which in turn connect to (4) upstream nuclei within the brain. This organization is already intricate from an anatomical perspective (see Chapter Gustatory Pathways in Fish and Mammals), but is truly a marvel of complexity when one considers its embryonic development. Taste buds develop *in situ* within the epithelia lining the oral and pharyngeal cavities, quite far from the developing brain. Likewise the sensory neurons destined to innervate taste buds also arise from neurogenic precursors outside of the brain. Finally, populations of hindbrain and higher order central neurons arise directly from specific regions of the forming neural tube. As we will review here, these elements each arise initially quite independently of, and at great distance from, the others, yet subsequently manage to connect to one another to produce a coordinated, fully functional taste system at birth (Figure 1).

In addition to these dynamic embryonic events, the taste system continues to develop postnatally. The cells within taste buds are constantly renewed throughout adult life, and the connections between the taste periphery and central targets remain plastic and modifiable by environmental influences. Despite this flexibility, we experience no alterations in our ability to taste.

In the past decade or so, studies of taste system development have been invigorated in large part by an expansion of experimental studies focused on embryonic development, as well as by use of transgenic mouse models in both embryonic and postnatal settings. These new approaches have provided new answers to major questions in the field: what are the molecular,

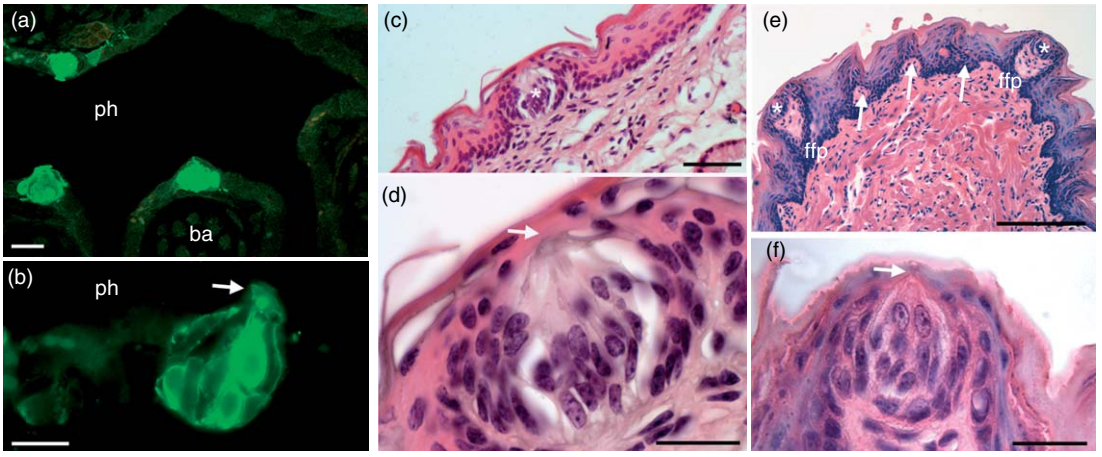

Figure 1 Depending upon the species or the location of taste buds within the oral cavity, taste buds can occur as discrete organs within the general epithelium or within more complex epithelial specializations. (a, b): Taste buds of juvenile axolotls (an aquatic salamander) are embedded directly in the oral and pharyngeal epithelia (ph; pharyngeal cavity). In these transverse sections through the pharyngeal region (dorsal is up), a subset of taste cells have been immunofluorescently stained (green) with antiserum against calretinin (Barlow, L. A. *et al.*, 1996). Note the characteristic onion shape of the taste organs and the narrow apical regions extruding into the pharyngeal cavity (arrow in b). (c, d): In mice, palatal taste buds are large and readily recognized as discrete organs within the epithelium. Again, these taste buds are found within the general epithelium, are onion-shaped (* in c), and narrow apically in the vicinity of the taste pore (arrow in d). (e, f): In contrast, taste buds on the mouse tongue are housed in elaborate papillae, including the fungiform papillae shown here (ffp). A single taste bud (* in e) sits in the apical papillary epithelium, while each papilla comprises an evaginated epithelium with a mesenchymal core. The fungiform papillae are interspersed with numerous, heavily keratinized filiform papillae (arrows in e). Despite their localization to fungiform papillae, the taste buds therein have the common onion shape and terminate apically in a narrow taste pore (arrow in f). Scale bars = 50 μm (a, c); 25 μm (b); 20 μm (d); 100 μm (e); 40 μm (f). (a, b, e, f) Transverse sections, dorsal is up. (c, d) Transverse sections, dorsal is down.

cellular, and tissue level interactions involved in taste organ development and patterning; how do sensory neurons come to innervate specifically both peripheral taste bud and central hindbrain targets; what types of cellular and molecular mechanisms maintain the mature taste system; and how well conserved are these developmental mechanisms in vertebrate evolution? These topics are thus the focus of our review.

4.06.2 The Taste Periphery: Of Buds and Bumps

To date, all vertebrate animals possess taste buds within the mouth and pharynx (although some fishes have external taste buds, see Gomahr, A. *et al.*, 1992; Reutter, K. and Witt, M., 1993; Hansen, A. *et al.*, 2002; Northcutt, R. G., 2005). These multicellular receptor organs are each composed of a mixed population of roughly 100 fusiform cells, which taper both apically and somewhat basally, to create an onion-shaped aggregate (Figure 2; and see Chapter Ultrastructure of Taste Buds). While this is the common organization for vertebrate taste buds, there is an extremely wide variety in the morphology of epithelial structures associated with taste buds proper. In their most simplified state, taste buds occur within the general epithelium, and are not associated with any specialized epithelial appendages or structures (Figure 2). This is the case for aquatic salamanders, such as the axolotl (Fährmann, W., 1967; Toyoshima, K. *et al.*, 1987; Northcutt, R. G. *et al.*, 2000), where taste buds are readily detected in the oropharyngeal epithelium simply by their multicellularity and classic onion shape. In mammals, taste buds in the palate, pharynx, and larynx are also simple and onion shaped, residing directly within the epithelia (Mistretta, C. M., 1972; Belecky, T. L. and Smith, D. V., 1990; Zhang, C. and Oakley, B., 1996). However, in numerous instances, taste buds occur in the epithelium of specialized structures. For example, in catfish and zebrafish, individual taste buds are associated with taste hillocks (Gomahr, A. *et al.*, 1992; Reutter, K. and Witt, M., 1993; Hansen, A. *et al.*, 2002; Northcutt, R. G., 2005), which are slight epithelial elevations with small mesenchymal cores (Figure 2). On the tongues of mammals, taste buds are restricted to elaborate

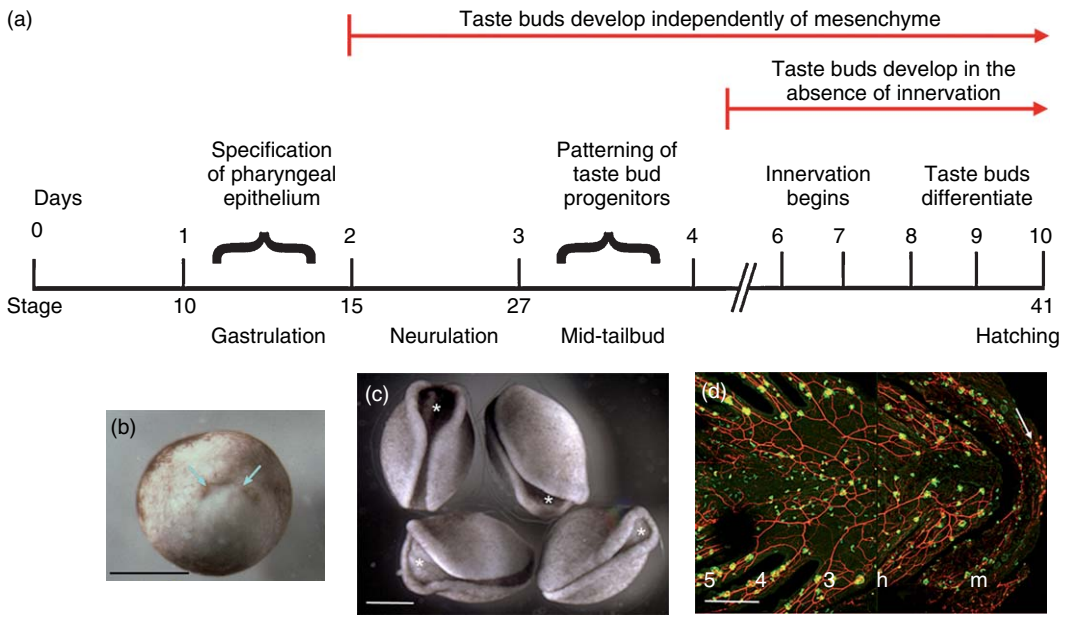

Figure 2 Time line of the experimental dissection of tissue level mechanisms governing taste bud development in axolotls. (a): Axolotl embryos develop from fertilization (day 0) to hatching (stage 41) over 10 days. Taste buds differentiate within a day of hatching, while the epithelium has already received innervation by 6 days. Nonetheless, taste buds develop in the absence of innervation (short red arrow; see text for full details). Further, taste buds develop in epithelium devoid of contact with cranial mesenchyme (long red arrow; see text). In fact, pharyngeal epithelium is specified by signals it receives during gastrulation and is patterned by tissue-intrinsic signaling during tailbud stages (horizontal brackets; see text). (b): At the onset of gastrulation, the dorsal blastopore lip is evident as a pigmented depression in the dorsal vegetal surface of an axolotl embryo (blue arrows; vegetal view). (c): During neurulation, the paired neural folds rise up from the dorsal surface of each axolotl embryo, and in this micrograph, the folds have approached the dorsal midline to fuse and form the neural tube. The anterior region (*s) will give rise to the forebrain and midbrain, while the more posterior folds produce the hindbrain and spinal cord. (d): At hatching, both differentiated taste buds and their extensive innervation are evident in the internal pharyngeal surface of the lower jaw of axolotls. Using confocal microscopy on a larval axolotl head processed in whole mount for double immunofluorescence, taste buds (green) are revealed with antiserum against calretinin, and antiacetylated tubulin allows detection of nerves (red). m: mandible; h: hyoid arch; 3, 4, 5: third, fourth, and fifth branchial arches. Scale bars = 1 mm (b–d). Image acquired by Mark A. Parker.

structures, termed taste papillae (Mistretta, C. M., 1972). These appendages are composed of epithelial evaginations and/or invaginations, surrounding substantial mesenchymal cores (Figure 2). Taste buds reside in the epithelia of gustatory papillae, and taste cells within each bud extrude their apical microvilli into the lumen of a tightly arranged taste pore. The number of taste buds housed in these papillae can vary from 1 to 3 per papilla, as is the case for the smaller fungiform papillae in the anterior tongue, to several hundred per papillae as is the case for the large, posterior foliate and circumvallate papillae (Figure 2). In sum, while the morphology of taste buds is quite similar among vertebrates, ancillary epithelial structures associated with taste buds differ widely. This latter variability may reflect different selective pressures on taste epithelium, including tasting in air versus in water, and the types of foods ingested by different animals.

Because aquatic salamanders have a taste bud organization uncomplicated by association with specialized epithelial structures, they perhaps can serve as a model for the most basic mechanisms driving the development of this system. Thus, that is where this review of new data on taste system development begins in earnest.

4.06.3 Development of the Taste Periphery: How Does Taste Bud Pattern Arise?

Recently, a number of studies providing insight into how taste buds develop have utilized either

amphibian (axolotl) or mammalian (mouse and rat) embryos. And therefore, we will first review the insights into taste periphery development gleaned from studies of axolotls, then present the new findings in rodents that speak to these same issues.

4.06.3.1 Taste Bud Development in Axolotls

Axolotls are a species of aquatic salamander native to the high altitude lakes in the vicinity of Mexico City (Smith, H. M., 1969), and embryos of this species and those of its close relatives have been an important tool in studies of embryogenesis for nearly a century (e.g., Vogt, W., 1929; Mangold, O., 1931; Nieuwkoop, P. D. and Ubbels, G. A., 1972; Slack, J. M. and Forman, D., 1980; Armstrong, J. B. and Malacinski, G. M., 1989). In the last decade, we have taken advantage of the ease of microsurgical manipulation of these embryos at virtually any stage of development to explore tissue-level and cellular mechanisms regulating taste bud formation.

Although taste buds are first evident morphologically in the oral cavity as axolotl larvae hatch and begin to feed (Barlow, L. A. and Northcutt, R. G., 1995), the oral and pharyngeal epithelia are innervated by gustatory nerve fibers long before, during mid- to late embryonic stages. This sequence of events, innervation followed by taste bud differentiation, is common to all vertebrates examined to date (Landacre, F. L., 1907; Stone, L. S., 1940; Farbman, A. I., 1965; Bradley, R. M. and Stern, I. B., 1967; Reutter, K. and Witt, M., 1993; Whitehead, M. C. and Kachele, D. L., 1994; Barlow, L. A. *et al.*, 1996; Witt, M. and Reutter, K., 1996; Northcutt, R. G., 2005); and when combined with studies employing adult vertebrates demonstrating that maintenance of mature taste bud morphology is dependent upon intact innervation (e.g., Vintschgau, M. and Honigschmied, J., 1876; Torrey, T. W., 1934; Poritsky, R. and Singer, M., 1963; but see Whitehead, M. C. *et al.*, 1987), has led to a neural induction model for taste bud formation. Specifically, this model posits that during development, early arriving nerve fibers induce taste buds to form from an otherwise homogeneous local epithelium.

Over 10 years ago, expanding on ectopic grafting studies first published by Stone L. S. (1932; 1940), the neural induction model was tested using axolotl embryos and modern immunocytochemical methods to detect all nerve fibers (Barlow, L. A. *et al.*, 1996). The oropharyngeal epithelium of amphibian embryos, destined to give rise to taste buds (Barlow, L. A. and Northcutt, R. G., 1995), was removed prior to innervation and cultured in isolation. Despite the complete absence of nerve contact, the explanted epithelia generated taste buds in appropriate densities and with a time course identical to that of intact embryos. Thus, at least in these amphibians, innervation is not required for taste bud formation.

Since taste buds are not induced by nerves, they might instead be induced by contact with cranial mesenchyme. This latter cell population contacts the oral epithelium during embryogenesis and is a known inducer of other tissues within the oral cavity, including teeth (Kollar, E. J., 1983; Lumsden, A. G. S., 1987; 1988) and cartilage (Graveson, A. C. and Armstrong, J. B., 1987). However, when oropharyngeal epithelia of early axolotl embryos are removed and cultured prior to and without subsequent contact with embryonic mesenchyme, taste buds still form in epithelial explants at the appropriate developmental stage, some 10 days later (Barlow, L. A., and Northcutt, R. G., 1997). Thus, taste bud development is independent of both nerves and cranial mesenchyme. Logically then, since no other tissues contact the oropharyngeal epithelium during embryogenesis, formation of taste buds is an intrinsic feature of this epithelium, one that is acquired early in embryonic development. In fact, this predisposition or specification (see Slack, J. M. W., 1991) to a taste bud-bearing fate is acquired during gastrulation and is due to signals from the embryonic notochord (Barlow, L. A., 2001). The implication here is that molecular signals from the notochord induce changes in the oropharyngeal epithelium such that the latter produces taste buds which differentiate 10 days later.

One unanticipated aspect of these results was how early the tissue-level interactions that set the stage for epithelium-intrinsic taste bud formation occurred – so much earlier than taste bud differentiation at the end of embryonic development. Given the large expanse of developmental time between the completion of gastrulation and taste bud differentiation 10 days later, how does this early intrinsic property transform into the patterned array of taste buds in the mouth? To address this question, we proposed that local cell–cell interactions were mediating pattern formation of presumed taste bud progenitor cells (Barlow, L. A. and Northcutt, R. G., 1998; Northcutt, R. G. and Barlow, L. A., 1998). To test if and when this was occurring, intercellular contacts were disrupted transiently in oropharyngeal epithelial explants at progressive developmental

stages. These studies reveal a critical 12 h window, again long before taste bud differentiation and innervation of the epithelium, during which cell–cell communication is crucial for determining taste bud pattern when intercellular signals are interrupted during this phase, the total number and size of individual taste buds is dramatically increased (Parker, M. A. *et al.*, 2004). This result has led to our hypothesis that a population of distributed taste bud progenitor cells is induced at this earlier stage, which later goes on to divide and give rise to taste bud cells proper, a hypothesis that remains to be tested.

4.06.3.2 Taste Bud Development in Rodents

In broad overview, the development of taste buds in mice and rats is quite comparable to that of axolotls. Taste buds arise directly from the oral epithelium (Stone, L. M. *et al.*, 1995; 2002) and do not differentiate until perinatal stages, the precise timing depending upon their location. The sequence of taste bud formation has been best studied in the tongue because the future location of these organs can be discerned quite early in development via changes in the morphology of subsets of cells within the lingual epithelium. For example, in the anterior two-thirds of the tongue, fungiform papillae are first evident as two parasagittal rows of columnar epithelial foci (Mistretta, C. M., 1972; Farbman, A. I. and Mbiene, J.-P., 1991). These epithelial thickenings are termed placodes, which grow and invaginate to surround and create the mesenchymal core of each papilla. At birth, an onion-shaped aggregate of immature taste cells is present in the apex of each papilla, which subsequently differentiates fully into a mature taste bud sometime within the first postnatal week. Key to this designation of full differentiation is the postnatal formation of a definitive taste pore, which is the gold standard for a functional taste bud (Hosley, M. A. *et al.*, 1987; Farbman, A. I. and Mbiene, J.-P., 1991; Harada, S. *et al.*, 2000).

Intriguingly, lingual taste buds of the fungiform, foliate, and circumvallate papillae are not fully differentiated at birth in rodents (Mistretta, C. M., 1972; Oakley, B. *et al.*, 1991; Sbarbati, A. *et al.*, 1999), yet newborn mice and rats suckle almost immediately, inferring that they must possess a functional taste system. In fact, it is likely that the taste buds residing in the epithelium of the palate subserve this early requirement for sweet taste sensation in rodent pups (Harada, S. *et al.*, 1997; Sollars, S. I. and Hill, D. L., 2005). Palatal taste buds, as a population, differentiate prior to birth, in that over half of them possess pores, compared to ~15–20% of fungiform taste buds in newborns (Harada, S. *et al.*, 2000; Zhang, G. H. *et al.*, 2006). This result has been corroborated employing immunocytochemistry for a marker of a subtype of differentiated taste cells (Boughter, J. D. *et al.*, 1997; Yang, R. *et al.*, 2000). Using antiserum against alpha-gustducin, the majority of palatal taste buds have gustducin-immunoreactive taste cells at birth (El-Sharaby, A. *et al.*, 2001a; 2001b), while gustducin immunoreactivity is not detected in lingual taste buds until later, during the first postnatal week (El-Sharaby, A. *et al.*, 2001b; Zhang, G. H. *et al.*, 2006).

Regardless of location, and as in axolotls, however, taste bud differentiation occurs well after nerves contact the developing epithelium (Farbman, A. I., 1965; Farbman, A. I. and Mbiene, J.-P., 1991; Mbiene, J.-P. and Mistretta, C. M., 1997; Mbiene, J.-P., 2004; Sharaby, A. E. *et al.*, 2006), consistent with a neural induction model.

The neural induction hypothesis has now also been tested explicitly in rodents via lingual explant culture. Several groups have shown that the formation of fungiform placodes is independent of innervation. When lingual primordia are removed prior to placode formation and then cultured in the absence of innervation, these explants first develop placodes, which then begin papillary morphogenesis (Farbman, A. I. and Mbiene, J.-P., 1991; Mbiene, J.-P. *et al.*, 1997; Nosrat, C. A. *et al.*, 2001; Hall, J. M. *et al.*, 2003; Mistretta, C. M. *et al.*, 2003; Liu, H. X. *et al.*, 2004). Unfortunately, these cultures do not survive long enough to allow taste bud differentiation, and thus the precise relationship between placodes, papillae, and the late developing taste buds is unclear. While a number of studies have examined the impact of loss of sensory neurons via a neurotrophin knockout strategy in mice, this approach has shown primarily that innervation is required postnatally for taste bud maintenance rather than for testing the role of nerves in taste organ formation. These results will be addressed fully later on.

Currently, the accepted model for taste organ development is that placodes arise independently of innervation and, in turn, form rudimentary papillae in the absence of nerves. Shortly before birth, taste bud progenitor cells are organized within a small region of the papillary epithelium, and this latter process is thought to be nerve dependent (Farbman, A. I. and Mbiene, J.-P., 1991; Oakley, B. and Witt, M., 2004; Mistretta, C. M. and Liu, H. X., 2006). A counterview is that placodes actually represent taste bud progenitors (Mbiene, J.-P. and Roberts,

J. D., 2003). Thus the taste progenitor pool arises in a nerve-independent fashion, while full differentiation of these cells is again thought to rely on innervation; however, this early progenitor interpretation is controversial (see Oakley, B. and Witt, M., 2004).

Regardless of the identity of the taste placode cells, that is, progenitors for papillae or for taste buds, it is generally believed that taste papilla development is governed via epithelial–mesenchymal interactions. This assumption is based on similarities with other epithelial specializations, such as hair follicles, teeth, and feathers (Mistretta, C. M., 1998; Yu, M. *et al.*, 2002; Pispa, J. and Thesleff, I., 2003), yet until very recently, experimental tests of this idea were lacking. Through a series of elegant epithelial/mesenchymal recombination experiments employing embryonic lingual explants, Kim J. Y. *et al.* (2003) have shown that there are indeed signals between the epithelium and mesenchyme during early papilla morphogenesis. Moreover, the pattern of placode formation appears to reside within the lingual epithelium, while papillary morphogenesis requires general signals from mesenchyme. This latter finding suggests, as has been shown in axolotls (Parker, M. A. *et al.*, 2004), that taste organ pattern in rodent embryos is set up initially via cell–cell interactions intrinsic to the lingual epithelium. Consistent with a role for intercellular communication, disruption of gap junctional contacts in cultured mouse tongues results in alterations in taste placode pattern (Kim, J. Y. *et al.*, 2005).

4.06.3.3 Molecular Mechanisms of Taste Patterning

In addition to experimental tests of tissue and cellular interactions, there has been an expansion of molecular investigations of developing taste buds. A number of groups have shown that genes belonging to powerful developmental signaling pathways are expressed in the embryonic tongue and taste organs. The pathways investigated include: Sonic Hedgehog (Shh), Bone Morphogenetic Protein (BMP), Wnt/β-catenin, fibroblast growth factor (FGF), and Notch. All of these pathways are key regulators of numerous aspects of embryonic development, as well as of adult tissue homeostasis (Shh: Chuong, C. M. *et al.*, 2000; Marti, E. and Bovolenta, P., 2002; BMP: Tanabe, Y. and Jessell, T. M., 1996; Botchkarev, V. A. and Sharov, A. A., 2004; Wnt: Wodarz, A. and Nusse, R., 1998; Ciani, L. and Salinas, P. C., 2005; FGF: Cornell, R. A. and Eisen, J. S., 2005; Dvorak, P. *et al.*, 2006; Notch: Blanpain, C. *et al.*, 2007).

In terms of taste organ patterning in rodent embryos, the Shh pathway is the most heavily studied to date. Shh is a secreted factor which is recognized by the transmembrane protein, Patched (Ptc) (see Athar, M. *et al.*, 2006). When Shh binds Ptc, this releases Smoothened (Smo), another transmembrane protein, from Ptc inhibition and activates an intracellular cascade, which in turn activates gene transcription. In particular, Shh signaling results in upregulation of Ptc and of the Glil transcription factor. Thus, Glil and Ptc expression are good indicators of active Shh signaling. In embryos, Shh ligand is present throughout the lingual epithelium as the tongue first forms from bilateral lingual swellings and becomes restricted to the columnar placodal epithelial cells as placodes arise. This focal Shh expression persists in papillae as they undergo morphogenesis (Bitgood, M. J. and McMahon, A. P., 1995; Hall, J. M. *et al.*, 1999; Jung, H. S. *et al.*, 1999; Mistretta, C. M. *et al.*, 2003; Liu, H. X. *et al.*, 2004). *Ptc* and *Gli1* are detected similarly throughout the lingual epithelium commencing with tongue formation but, unlike Shh, are also expressed in the subepithelial mesenchyme (Hall, J. M. *et al.*, 1999). Both epithelial and mesenchymal expression of *Ptc* and *Gli1* become progressively limited to the forming taste papillae, until both of these genes are detected in the epithelium in rings surrounding the Shh-expressing cells, as well as within the mesenchymal core of each papilla. In sum, these expression patterns are consistent in time and place with an important role for Shh signaling in taste organ development.

Expression of the BMP pathway has also been examined in the developing tongue of rodent embryos (Jung, H. S. *et al.*, 1999; Hall, J. M. *et al.*, 2003; Nie, X., 2005). BMPs comprise a small subfamily belonging to the large transforming growth factor-β (TGFβ) family of secreted factors (Kingsley, D. M., 1994). BMP ligands bind to heterodimeric BMP receptors which, through a series of transphosphorylations, result in activation of SMAD transcription factors, and thus of target gene transcription (Balemans, W. and Van Hul, W., 2002). BMP signaling is tightly regulated by a host of native, secreted antagonists, of which Noggin was the founding member (Zimmerman, L. B. *et al.*, 1996). When mRNA or protein for several BMP ligands is examined, low-level expression appears to commence throughout the epithelium and mesenchyme of the tongue rudiment as it forms (Jung, H. S. *et al.*, 1999; Zhou, Y. *et al.*, 2006). Expression, especially of *BMP4*,

then consolidates within the developing placodal epithelium, coincident with Shh expression. In fact, there is a one-to-one correspondence between placodal cells expressing BMP4 and those expressing Shh (Hall, J. M. *et al.*, 2003). BMP4 protein is also detected within the subepithelial mesenchyme as papillae develop, whereas its mRNA is not, suggesting that the epithelial cells of the papillae are the source for the diffusible BMP4 found in the mesenchyme (Zhou, Y. *et al.*, 2006). Expression of most other genes of the BMP pathway has yet to be examined in the developing tongue, with the exception of Noggin, a secreted BMP2, 4, and 7 antagonist; Noggin-immunoreactivity is detected in a pattern similar to that described above for the BMP ligand (Zhou, Y. *et al.*, 2006). Like Shh, the timing and pattern of BMP expression is consistent with a role in taste organ formation and patterning.

Most recently, expression of the Wnt/β-catenin pathway has been explored in the developing taste periphery of mouse embryos. Wnts are secreted ligands, comprising 19 members to date (see Relevant Website section). The Wnt signal is transduced by several distinct, yet likely interacting, intracellular pathways (Moon, R. T. *et al.*, 2002; Bejsovec, A., 2005; Widelitz, R., 2005). Of these, the β-catenin pathway is the best studied (Wodarz, A. and Nusse, R., 1998). In the Wnt/β-catenin signaling cascade, Wnt ligands bind Frizzled receptors, which complex with intracellular proteins to inhibit the action of the GSK3β protein kinase. In the absence of Wnt, GSK3β phosphorylates β-catenin, thus targeting the latter for degradation. When Wnt is present, however, β-catenin is not degraded, and accumulates to sufficient levels to translocate to the nucleus and contribute to a transcriptional activating complex with TCF and LEF transcription factors. In this way, Wnt-responsive target genes are activated.

Wnt expression is evident in developing mouse tongues coincident with the appearance of taste placodes. In particular, *Wnt10b* is restricted to placodal epithelium, while *Wnt10a* is found broadly throughout the lingual epithelium as taste placodes form (Iwatsuki, K. *et al.*, 2007; Liu, F. *et al.*, 2007). Similarly, *Lef1*, a downstream transcription factor of the Wnt/β-catenin pathway is expressed in taste placodes and later in taste papilla epithelium (Iwatsuki, K. *et al.*, 2007). Via use of mice expressing a Wnt/β-catenin reporter transgene (TOPGAL transgenic strain; DasGupta, R. and Fuchs, E., 1999), the location of Wnt-responsive cells has also been determined. The TOPGAL gene reveals active Wnt/β-catenin signaling in the lingual epithelium commencing as taste placodes form, and consistent with *Wnt10b* focal expression (Okubo, T. *et al.*, 2006; Iwatsuki, K. *et al.*, 2007; Liu, F. *et al.*, 2007). However, TOPGAL expression is also evident at these early stages in the intervening epithelial cells destined to give rise to filiform, that is, nongustatory, papillae of the lingual surface (Liu, F. *et al.*, 2007). Intriguingly, TOPGAL expression becomes increasingly restricted in the lingual epithelium, such that immediately prior to birth, it is detected only in immature taste buds in the apices of the fungiform papillae (Liu, F. *et al.*, 2007). Thus, Wnt/β-catenin signaling is implicated in taste organ formation, and possibly taste bud differentiation, by virtue of its spatiotemporal pattern of expression.

Compared with the extensive data on Shh, BMP, and recently Wnts, there is far less information on the expression of the FGF and Notch pathways in developing tongues. The FGF family comprises 22 genes to date, with numerous splice variants, which bind to FGF receptors (FGFRs 1–4; Itoh, N. and Ornitz, D. M., 2004). mRNA for several FGF ligands and a variety of FGFRs have been detected in the developing tongues of mice (Jung, H. S. *et al.*, 1999; Nie, X., 2005). *Fgf8*, which is known to function in early branchial arch patterning (Abu-Issa, R. *et al.*, 2002; Crump, J. G. *et al.*, 2004), is expressed in the lingual epithelium and subepithelial mesenchyme in the lateral lingual swellings prior to their fusion into the tongue rudiment (Jung, H. S. *et al.*, 1999). By the time the tongue proper has formed and taste placodes begin to appear, however, *Fgf8* expression is lost, suggesting that FGF8 functions in tongue formation, but does not have a direct role in taste placode formation.

The Notch pathway has numerous roles in cell fate decisions throughout embryonic development. Notch is a transmembrane receptor, which recognizes several transmembrane ligands, including Delta-like (Dll) and Jagged (or Serrate), in adjacent cells. When the Notch receptor is activated, gamma secretases cleave N, generating the N intracellular domain (N_{ICD}), which translocates to the nucleus and affects target gene transcription (Artavanis-Tsakonas, S., 1988; Cornell, R. A. and Eisen, J. S., 2005). In particular, in the developing nervous system and in neural stem cells, activated Notch signaling turns on transcription of Hes transcription factor genes and these cells assume a glial fate or remain undifferentiated; while cells in which Notch is not active transcribe neurogenic genes, such as Mash1, and assume a neural fate (Gaiano, N. and Fishell, G., 2002). In the developing tongue, Notch gene expression is not detected until well after Wnt,

Shh, and BMP expression have become focal within developing papillae (Seta, Y. *et al.*, 2003). As the papillae undergo morphogenesis, several Notch receptors and ligands are expressed broadly in the papillary epithelium. The transcription factors, *Mash1* and *Hes6,* by contrast, are expressed in small numbers of epithelial cells during papillary development (Seta, Y. *et al.*, 2003). Thus, while Shh, Wnt, and BMP expression are coincident with placode formation, Notch signaling appears to function later on, during papillary morphogenesis, and thus may regulate cell fate decisions within taste papillae.

4.06.3.4 Tests of Gene Function in Taste Organ Formation and Patterning

Recent tests of Wnt, Shh, and BMP function have revealed roles for each of these pathways in early taste organ development, as was predicted based upon the spatiotemporal expression of these genes. Perhaps the most complete studies have come from manipulation of Wnt/β-catenin, where the levels of signaling by this pathway have been altered genetically *in vivo* and via pharmacological manipulation *ex vivo* (Iwatsuki, K. *et al.*, 2007; Liu, F. *et al.*, 2007).

Using tissue-specific and inducible transgenic mouse lines, Wnt/β-catenin signaling was completely abolished within the lingual epithelium of mouse embryos, commencing just prior to the onset of taste placode formation. In these knockdown and knockout embryos, placodes are not evident, nor are evaginated papillae present at birth (Liu, F. *et al.*, 2007). Similarly, papillae are reduced, although not lost, in both Lef1$^{-/-}$ and Wnt10b$^{-/-}$ mice (Iwatsuki, K. *et al.*, 2007), implying that these two genes are not the only Wnt signaling genes involved in taste placode and papillary development. Conversely, when β-catenin is stabilized, that is, genetic alteration having rendered β-catenin resistant to degradation throughout the embryonic lingual epithelium, the entire lingual surface is transformed into taste papillae. Moreover, filiform papillae are absent, and taste buds within the taste papillae appear to have accelerated development (Liu, F. *et al.*, 2007).

Wnt/β-catenin signaling also appears to function as an initiator signal for taste placode formation, as it is upstream, at least genetically, of both Shh and BMPs. When Wnt/β-catenin signaling is lost, *Shh* is not expressed in the lingual epithelium, consistent with the observed loss of placodes. Similarly, *BMP4* is not expressed in the lingual epithelium of mouse embryos with epithelial loss of Wnt/β-catenin function (Liu, F. *et al.*, 2007). Moreover, in the gain-of-function genetic manipulation, as well as *ex vivo* when Wnt/β-catenin signaling is increased pharmacologically, *Shh* expression is increased, in that *Shh* placodal expression is expanded (Iwatsuki, K. *et al.*, 2007; Liu, F. *et al.*, 2007). Wnt/β-catenin is also upstream of Sox2, a transcription factor recently shown to be required for taste organ development (Okubo, T. *et al.*, 2006); elevation of Wnt/β-catenin signaling in cultured tongue explants increases Sox2-expressing taste placodes.

The role of Wnt/β-catenin as a positive regulator of Shh signaling, however, appears to be reciprocal, in that manipulation of Shh in cultured tongue explants alters expression of Wnt activity, as monitored by the TOPGAL reporter gene (Iwatsuki, K. *et al.*, 2007). Substantial data also implicate a key role for Shh in taste placode formation. When Shh is blocked in cultured tongue explants, taste placodes increase in number and size and occur closer together (Hall, J. M. *et al.*, 2003; Mistretta, C. M. *et al.*, 2003), while Shh ligand blocks papillary formation (Iwatsuki, K. *et al.*, 2007). These effects are clearly indirect, however, as blocking Shh causes placodal Shh expression to expand, as do taste papillae, while increasing Shh signaling *in vitro* causes loss of Shh expression just as taste papillae are lost. Moreover, Shh also regulates BMP4; Shh inhibition *in vitro* increases the number and size of BMP4-expressing placodes (Hall, J. M. *et al.*, 2003). Recently, BMPs have also been implicated in regulation of Shh in developing taste papillae (Zhou, Y. *et al.*, 2006). Again, using a culture approach, antagonizing BMP in lingual explants results in more and larger papillae, with commensurate increases in Shh expression, while exposure to BMPs reduces papillae and Shh expression. In sum, these functional data suggest that the molecular regulation of taste placode formation relies upon a network of interactions of at least the Wnt/β-catenin, Shh, and BMP pathways, which are likely integrated by additional intracellular and extracellular mechanisms.

4.06.4 Development of the Circumvallate Papilla, a Specialized Structure in Mammals

Until now, this review has focused on development of fungiform papillae and their resident taste buds, which arise as a distributed array on the anterior two-thirds of the tongue. However, mammals possess additional lingual taste buds housed in complex, and

large, papillae at the posterior portion of the lingual tongue; these are the circumvallate and foliate papillae. In adult rodents, each of these structures possesses hundreds of taste buds embedded in the epithelia lining the trenches and folds of the circumvallate and foliate papillae, respectively. The circumvallate papilla in particular is known to have a number of additional anatomical specializations. von Ebner's glands (also known as posterior deep lingual glands) empty directly into the circumvallate trenches (Sbarbati, A. *et al.*, 2002; Lee, M. J. *et al.*, 2006; Suzuki, Y., 2006). Additionally, the mesenchymal core of the circumvallate is associated with a circumvallate ganglion (Graziadei, P. P. and Graziadei, G. A., 1978; Sbarbati, A. *et al.*, 2000). Thus, the development of the circumvallate papilla involves the coordinated formation of a complex taste organ, in concert with glandular and ganglionic components.

The circumvallate papilla of rodents begins to develop quite early, as the lateral lingual swellings of the tongue first fuse at the midline. At this time point, the epithelium of the future circumvallate has already begun to thicken (Jitpukdeebodintra, S. *et al.*, 2002). Shortly thereafter, it is recognizable as a broad epithelial thickening or placode, also visible on the dorsal surface of the tongue, coincident with the appearance of fungiform placodes (Paulson, R. B. *et al.*, 1985; AhPin, P. *et al.*, 1989; Wakisaka, S. *et al.*, 1996; Mbiene, J.-P. and Roberts, J. D., 2003). Subsequently, the lateral walls of the presumptive papillae invaginate and grow ventrally, surrounding a large mesenchymal core, which is invaded by neuroblasts of the papillary ganglion. Trench invagination continues, due to cell proliferation localized primarily to the growing tips of the trench epithelium (Lee, M. J. *et al.*, 2006), for the remainder of embryogenesis and into postnatal stages (Mistretta, C. M., 1972; Sbarbati, A. *et al.*, 2000; Jitpukdeebodintra, S. *et al.*, 2002). The trenches are thought to give rise to the von Ebner's glands via branching morphogenesis commencing late in embryonic development (Jitpukdeebodintra, S. *et al.*, 2002; Lee, M. J. *et al.*, 2006). The taste buds first differentiate within the circumvallate epithelium several days after birth (Mistretta, C. M., 1972; Oakley, B. *et al.*, 1991), although onion-shaped aggregates of cells considered to be immature taste buds are evident at birth in rodents (Mistretta, C. M., 1972).

Given the complex nature of the circumvallate papilla, are the molecular mechanisms governing its formation similar to those involved in fungiform development? At first glance, they may not be. Although both *Shh* and BMP4 are expressed in the developing circumvallate papilla (Hall, J. M. *et al.*, 1999; 2003; Lee, M. J. *et al.*, 2006), alterations in Shh signaling *in vitro* do not appear to affect circumvallate morphology or Shh expression therein (Hall, J. M. *et al.*, 2003; Mistretta, C. M. *et al.*, 2003; Liu, H. X. *et al.*, 2004). BMP2 and BMP4 do not appear to be expressed in the developing circumvallate, nor does manipulating BMP signaling in tongue explants appear to affect this papilla (Zhou, Y. *et al.*, 2006). Further, evidence of Wnt/β-catenin signaling was not observed by us in the developing circumvallate papilla (Liu, F. *et al.*, unpublished observation), suggesting that Wnt/β-catenin may not be active in this taste structure during embryogenesis. Thus, it appears that molecular mechanisms distinct from those involved in fungiform placode formation likely regulate circumvallate development. This dichotomy may be due to the increased complexity of this posterior taste papilla or may reflect an endodermal origin (Zhang, C. and Oakley, B., 1996).

Specifically, the oral cavity marks the boundary between the surface ectoderm and the foregut endoderm, although precisely where the border lies in rodents has been a topic of conjecture. One possibility, based on differential cytokeratin expression, is that the circumvallate lies in the endodermal epithelium, while the fungiform taste buds arise from ectoderm covering the anterior portion of the tongue (Zhang, C. and Oakley, B., 1996). Another molecular correlate of this supposition is that cytokeratin 14 (K14) is expressed in the epithelium of the anterior two-thirds of the embryonic tongue, encompassing the fungiform domain, yet is absent from the posterior third of the lingual epithelium where the circumvallate forms (Liu, F. *et al.*, 2007). This difference in K14 expression may indicate that each region arises from a different germ layer, fungiform from ectoderm, circumvallate from endoderm, or may simply reflect different molecular regulation of anterior versus posterior taste organs due to differences in their complexity.

4.06.5 Taste Bud Cell Lineage and Turnover

Postnatal taste buds comprise a heterogeneous population of approximately 100 cells, divided into roughly three cell types, I, II, and III, based upon ultrastructure and molecular markers (see Chapters Ultrastructure of Taste Buds and Taste Receptors). Briefly, type I cells are thought to function as glia,

while types II and III are taste receptor cells. Type II cells express numerous bitter, sweet, and umami receptors and lack clear morphological synapses. In contrast, type III cells possess synapses and the transduction machinery for sour tastants. However, the intrigue from a developmental biologist's perspective in investigating mature taste buds is that the cells within each bud are continually replaced at a rapid pace, raising the questions of how taste cells are related to one another within a bud, and what is the nature of the cell lineage(s) that produces taste bud cells. Our current knowledge of taste cell turnover is limited primarily to birthdating studies for differentiated taste cell types.

Immature taste cells are thought to arise as a result of asymmetric division of between 7 and 13 putative stem or progenitor cells per taste bud (Beidler, L. M. and Smallman, R. L., 1965; Farbman, A. I., 1980; Stone, L. M. *et al.*, 2002). After ~3 days, taste cells differentiate, expressing appropriate cell type immuno-markers (Zhang, C. *et al.*, 1995; Cho, Y. K. *et al.*, 1998; Hirota, M. *et al.*, 2001). The relationship among cells of each bud is unclear, although type I cells likely represent a distinct lineage (Farbman, A. I., 1980). In terms of types II and III cells, either these are distinct cell lineages (Hamamichi, R. *et al.*, 2006), or a subset of type III cells may also give rise to type II cells (Miura, H. *et al.*, 2005; Ueda, K. *et al.*, 2006). Finally, taste cells are relatively short lived, as they die, via programmed cell death, on average 10 days after birth (Beidler, L. M. and Smallman, R. L., 1965; Farbman, A. I., 1980; Delay, R. J. *et al.*, 1986). However, it appears that not all taste cells have equivalent residence times in the taste bud. For example, in Farbman's tritiated thymidine birthdating study, he found that while the average lifespan for a likely type I or glial cell was 9 days, the persistence of type II receptor cells could be detected for as long as 25 days (Farbman, A. I., 1980). More recently, this finding has been confirmed using BrdU birthdating in combination with taste cell-type markers for types II and III (Hamamichi, R. *et al.*, 2006). A very short-lived population of cells is detected in taste buds with an average life span of 2 days, while a small proportion of type II and III cells are long-lived residents in the taste bud, detectable after 21 days. This perdurance of type II and III cells may reflect more elaborate differentiation and functional requirements for receptor cells compared with glial cells; the latter might be replaced on a shorter time frame. Alternatively, the very short lived cells may be immature taste cells of all three types and indicate that taste bud stem cells continually produce an overabundance of immature cells to quickly accommodate injury or any errors in cell lineage decisions.

While it is well recognized that taste buds continually turn over, the molecular regulation of this process is unknown. Certainly a large number of regulatory genes and transcription factors are expressed in subsets of adult taste cells, implying that these factors function in taste cell turnover and lineage decisions within buds. For example, several embryonic signaling pathways persist in adult taste buds. *Shh* is expressed in a small number of rounded cells in the basal compartment of each taste bud, while the Shh receptor, *Ptc1*, localizes to cells surrounding the bud (Miura, H. *et al.*, 2001; 2003). Elements of the Notch pathway are also found in adult taste buds, including Notch receptors and ligands, as well as downstream transcription factors (Kusakabe, Y. *et al.*, 2002; Suzuki, Y. *et al.*, 2002; Miura, H. *et al.*, 2003; Seta, Y. *et al.*, 2003; Hamamichi, R. *et al.*, 2006; Seta, Y. *et al.*, 2006). In addition, a number of other signaling pathways not well described in embryonic taste organ development are present in adult taste buds, including the EGF pathway (McLaughlin, S. K., 2000; Sun, H. and Oakley, B., 2002) and the insulin-like growth factor (IGF) pathway (Suzuki, Y. *et al.*, 2005). Consistent also with a role in taste cell turnover, loss of expression of many of these gene products occurs when taste buds are denervated in nerve injury experiments, which are known to cause a transitory loss of taste buds, including *Shh* (Miura, H. *et al.*, 2004), *Mash*1(Seta, Y. *et al.*, 1999), and NeuroD, a transcription factor in the Notch pathway (Suzuki, Y. *et al.*, 2002). In each of these cases, as the nerve regenerates, taste buds reappear, as does the expression of these factors. However, these data are correlative. To elucidate the function of these gene pathways in taste cell turnover and to perhaps gain insight into the lineage relationships of taste cells within buds, inducible genetic manipulations will have to be employed.

Innervation is also known to regulate taste bud differentiation and maintenance, and this topic will be considered fully in a later section.

4.06.6 Development of Gustatory Innervation

The other major focus of this review is to discuss the development of the gustatory sensory neurons which contact taste buds in the lingual epithelium and

convey taste information to the gustatory centers of the hindbrain. As mentioned in the introduction, the neurons that reside in the gustatory cranial ganglia arise embryonically from two neurogenic tissues that form both outside of the developing neural tube and distant from the oral epithelium. These two populations of developing sensory neurons must first locate one another and coalesce into a ganglion. They then send out both peripheral and central neurites to pathfind to the proper targets and make appropriate synaptic connections with taste buds and hindbrain neurons, respectively.

4.06.6.1 Development of the Sensory Neurons of the Gustatory Ganglia

Sensory neurons of the VII, IX, and X cranial nerve ganglia convey gustatory information from the mouth, pharynx, and larynx to the brain. Neurons of each of these ganglia arise from two discrete embryonic regions: the epibranchial placodes and a subset of the cranial neural crest (Narayanan, C. H. and Narayanan, Y., 1980; D'Amico-Martel, A. and Noden, D. M., 1983; Barlow, L. A. and Northcutt, R. G., 1995; Northcutt, R. G. and Brändle, K., 1995; Gross, J. B. *et al.*, 2003). Epibranchial placodes are a series of epithelial thickenings, which form in the ectoderm just dorsal to the branchial arches as the neural tube fuses. These placodes are neurogenic, in that they are mitotically active, producing immature neuroblasts which then migrate to assemble into portions of cranial ganglia VII, IX, and X (Webb, J. F. and Noden, D. M., 1993; Baker, C. V. and Bronner-Fraser, M., 2001; Begbie, J. and Graham, A., 2001a; Begbie, J. *et al.*, 2002; Schlosser, G., 2006). The cranial neural crest is a migratory population of cells, which gives rise to a broad variety of derivatives, including a portion of the sensory neurons and all of the glial cells of the VII, IX, and X cranial ganglia (Le Douarin, N. M. and Kalcheim, C., 1999).

Based primarily upon descriptive studies in catfish, it has been proposed that the epibranchial placodes give rise to the gustatory neurons of each ganglion. Catfish are rather unique with respect to the taste system; they have thousands of external taste buds distributed in the skin covering their head and trunk (Landacre, F. L., 1907; Atema, J., 1971; Reutter, K. *et al.*, 1974; Caprio, J. *et al.*, 1993). Regardless of location, these external taste buds are all innervated by a recurrent branch of the VII cranial nerve, and the ganglion for this nerve is greatly enlarged in catfish (Herrick, C. J., 1903; Kohbara, J. *et al.*, 1992). In examining the developing epibranchial placode of the VII ganglion, Landacre found that it was also enlarged, and its size correlated with the size of the VII ganglion itself and with the vast number of taste buds this nerve innervates in catfish (Landacre, F. L., 1907; 1910). More recently, using grafting and transgenic technology in axolotls, we find that indeed epibranchial placodes give rise to sensory neurons that exclusively innervate taste buds (Harlow, D. and Barlow, L. A., in preparation). Moreover, neural crest-derived sensory neurons in these same ganglia provide only somatosensory innervation to the oral and pharyngeal epithelium, and never innervate taste buds. Thus despite coalescence of these two cell populations within the ganglia providing gustatory innervation to the oral cavity, the mature function of these neurons is determined by their embryonic origin.

Once these sensory neurons have come together to form the nascent cranial ganglia, these cells begin to send out processes both distally and proximally to pathfind to their peripheral taste bud and central nervous system (CNS) targets.

4.06.6.2 Development of Peripheral Taste Innervation

In rodents, fungiform taste buds and taste papillae are innervated by the chorda tympani (gustatory) branch of the VII nerve and the lingual (somatosensory) branch of the V nerve, while the circumvallate receives both gustatory and somatosensory innervation from the glossopharyngeal (IX) nerve. Fungiform innervation commences shortly after ganglion formation as the chorda tympani and lingual nerve fibers penetrate the base of the developing tongue rudiment (Mbiene, J.-P. and Mistretta, C. M., 1997; Scott, L. and Atkinson, M. E., 1998; Mbiene, J.-P., 2004), while the glossopharyngeal nerve enters the tongue 1 day later (Mbiene, J.-P. and Mistretta, C. M., 1997). Almost immediately after entering the tongue, the chorda tympani and lingual nerves, which have thus far traveled into the tongue as a unitary bundle, now defasciculate, and branches of each nerve extend toward the dorsal epithelial surface (Mbiene, J.-P., 2004). During this initial sensory innervation, the bulk of sensory fiber growth into the tongue in both rats and mice is from the chorda tympani nerve; growth of lingual fibers appears to follow the chorda tympani into the tongue (Rochlin, M. W. and Farbman, A. I., 1998; Mbiene, J.-P., 2004). As chorda tympani axons approach the epithelial surface they branch profusely. However, even 1 day prior to target

innervation (at E13.5 in mice), only a few nerve bundles are specifically directed toward developing fungiform placodes (Mbiene, J.-P., 2004). In mice at this age, many nerve bundles have been described as having brush-like endings with numerous filopodia (Mbiene, J.-P., 2004). If so, these endings could be sampling the local environment to locate molecular cues that then guide the fiber bundles to individual fungiform placodes. Once chorda tympani fiber bundles are close to the epithelial surface they begin to grow toward taste placodes. Although lingual nerve bundles branch as they near the epithelial surface, growth of lingual fibers is not directed toward fungiform placodes (Mbiene, J.-P., 2004).

The initial progression of chorda tympani and lingual innervation in the tongue varies considerably among species, even between different rodents. In rats and mice, the chorda tympani is the first nerve to enter the tongue followed by the lingual fibers, while in hamsters, the lingual nerve is the first to enter the tongue and provides the bulk of its innervation (Whitehead, M. C. and Kachele, D. L., 1994). Also, unlike lingual innervation in rats and mice, the lingual nerve bundles in hamsters are actually directed toward fungiform papillae, with chorda tympani nerve bundles following (Whitehead, M. C. and Kachele, D. L., 1994).

By E14 in hamster, E14.5 in mouse, and E16 in rat, chorda tympani fibers have entered the core of the fungiform papillae and are clearly associated primarily with gustatory organs (Figure 3(a); Farbman, A. I. and Mbiene, J.-P., 1991; Whitehead, M. C. and Kachele, D. L., 1994; Mbiene, J.-P., 2004). By E16.5–E17 in rat and E14.5–E15 in mouse, chorda tympani fibers first penetrate the epithelium of individual taste papillae (Farbman, A. I., 1965; Farbman, A. I. and Mbiene, J.-P., 1991; Hall, J. M. *et al.*, 1999; Mbiene, J.-P. and Roberts, J. D., 2003). Initial innervation is sparse, but additional fibers continue to invade the epithelium at later embryonic ages. Synapse-like structures between gustatory afferents and fungiform taste buds are first observed several days after the initial innervation of fungiform papillae (Mbiene, J.-P. and Farbman, A. I., 1993). The sequence of events is comparable for the circumvallate papilla; glossopharyngeal fibers invade the circumvallate papilla core by mid-gestation and occasionally penetrate the epithelial surface (Figure 5(b); Mbiene, J.-P. and Mistretta, C. M., 1997). Circumvallate taste buds appear within the epithelial trenches and develop synapses during early postnatal development (Kinnamon, J. C. *et al.*, 2005). During this time, a robust neural plexus surrounds the taste bud; in addition to afferent synapses, this neural plexus contains neuroneuronal synapses. The role of this neural plexus is unclear, but it could be important for organizing initial taste bud–neuron connectively.

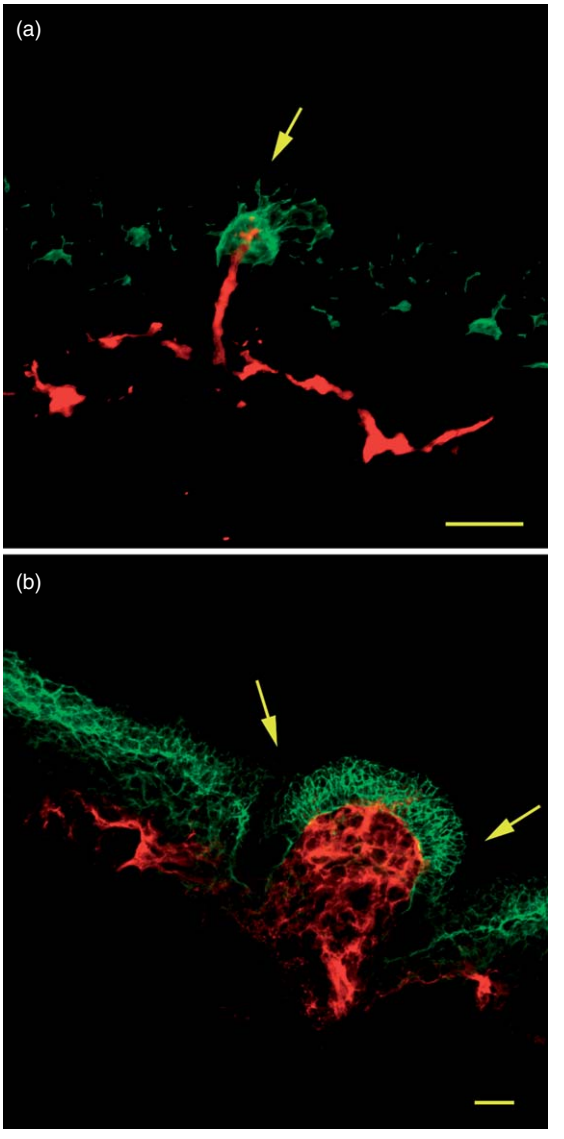

Figure 3 By E14.5 in the mouse, developing gustatory epithelia (anti-Shh; green) are associated with nerve fibers (anti-GAP43; red). Innervation has penetrated the epithelia of the developing fungiform papillae (a. arrow), although a neural bud is not yet present. The core of the developing circumvallatc papillae is filled with nerve fibers (b, between arrows). Scale bar = 20 μm.

Because chorda tympani nerve bundles are already associated with newly formed fungiform papillae by E14.5, the accuracy of initial targeting can be quantified at this age (Figure 4; Lopez, G. F. and Krimm, R. F., 2006b). This early targeting is incredibly accurate

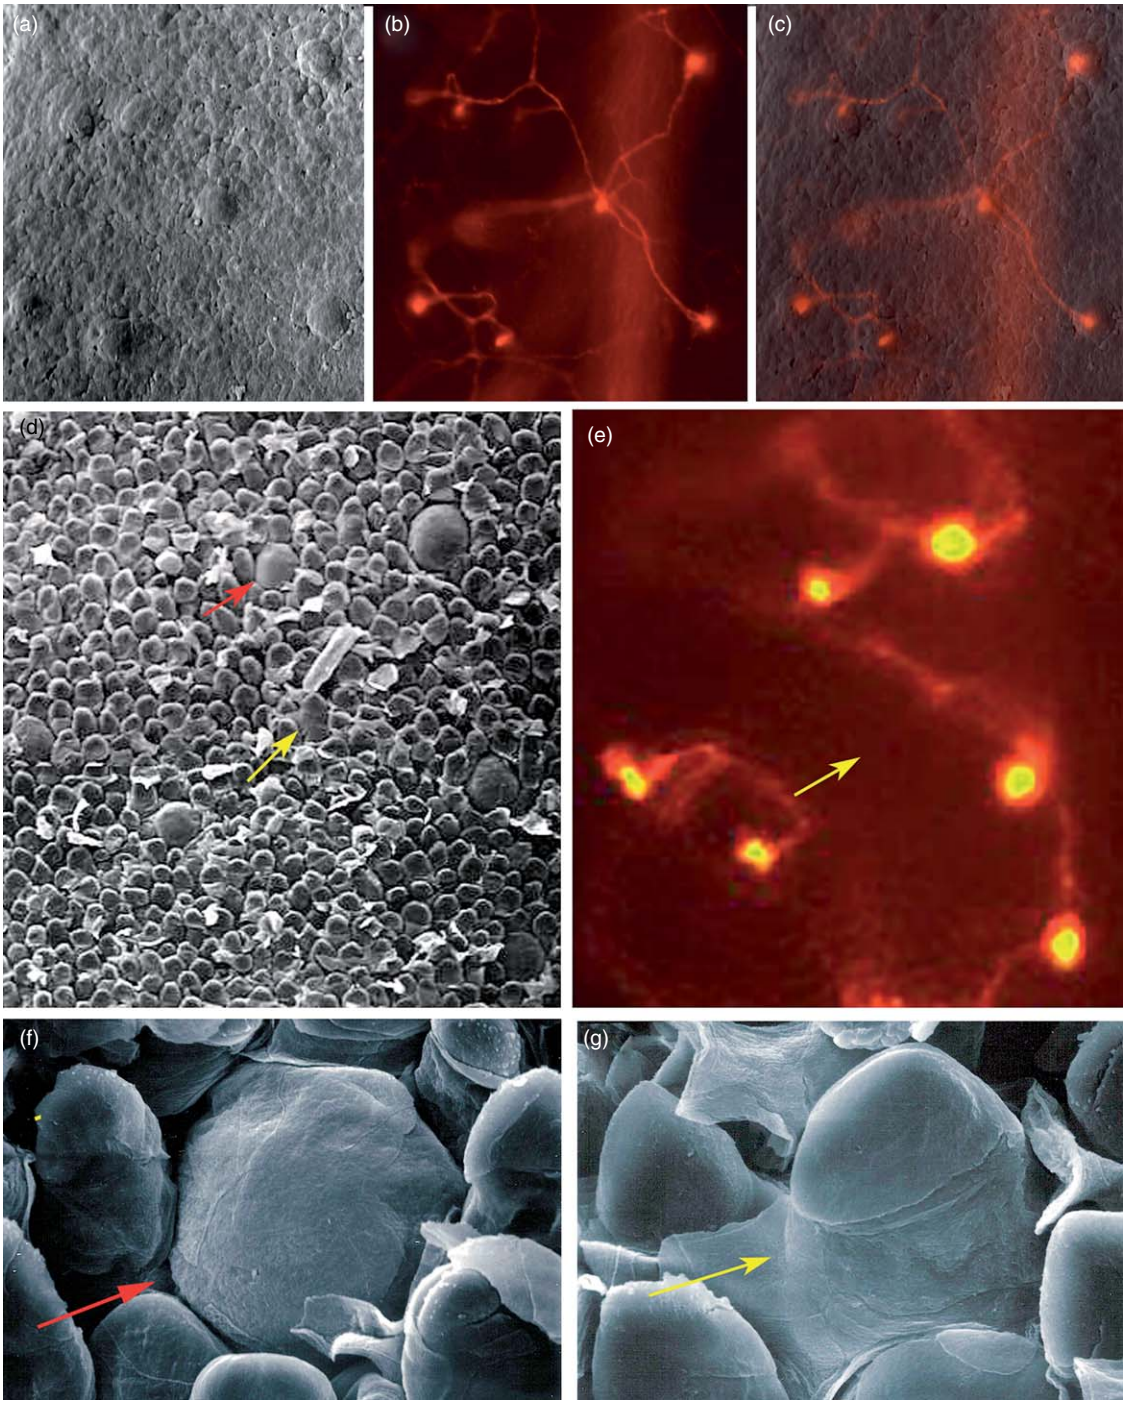

Figure 4 The locations of fungiform papillae (a,d) and innervation patterns (b,e) can be visualized in the same tongues by labeling first with DiI and then processing for scanning electron microscopy. Most fungiform papillae are innervated at both E14.5 (a,b,c) and E18.5 (d,e,f,g), although a few remain uninnervated. By E18.5, any uninnervated papillae (yellow arrow in d,g) have begun to adopt a morphology more similar to surround filiform papillae. Innervated papillae (red arrow in d and f) have a normal appearance.

in that most fungiform papillae are innervated and most fiber bundles are associated with a fungiform papilla. However, a few fungiform papillae are lacking innervation, and the chorda tympani innervates a few regions of the tongue that have no papillae. Between E14.5 and E18.5, most fungiform papillae previously lacking innervation now receive innervation, and any aberrant fiber bundles withdraw from nongustatory epithelium. Thus, a period of embryonic plasticity and rearrangement follows initial innervation.

Although the path gustatory axons take to their final destination is well described, axon guidance mechanisms are less clear. *In vitro*, initial axon outgrowth from gustatory ganglia requires addition of a neurotrophin to the culture media (Rao, H. *et al.*, 1997; Rochlin, M. W. *et al.*, 2000; Wiklund, P. and Ekstrom, P. A., 2000). Neurotrophins are a group of structurally and functionally related growth factors that exert a major influence on numerous aspects of sensory and sympathetic neuron development. The neurotrophins, brain-derived neurotrophic factors (BDNFs), neurotrophin-4 (NT4), and glial-derived neurotrophic factors (GDNFs) are capable of supporting neurite outgrowth of geniculate ganglion (VII) neurons, while neurotrophin-3 (NT3) and nerve growth factor (NGF) are not (Rao, H. *et al.*, 1997; Rochlin, M. W. *et al.*, 2000). Interestingly, removal of BDNF or NT4 does not disrupt the ability of chorda tympani axons to reach the tongue (Lopez, G. F. and Krimm, R. F., 2006a), indicating that neurotrophins are also functionally redundant for supporting initial axonal outgrowth *in vivo*.

Because the growth of chorda tympani axon bundles appears to follow predetermined pathways (Mbiene, J.-P. and Mistretta, C. M., 1997), the chorda tympani is probably guided by molecular cues in the environment. It is likely that multiple chemoattractive and chemorepulsive cues are required to direct gustatory axons from the geniculate (nVII) and petrosal (nIX) ganglia to the tongue and then to individual fungiform and circumvallate placodes (Tessier-Lavigne, M. and Goodman, C. S., 1996). For example, one factor produced by the tongue mesenchyme may encourage initial tongue innervation. A second factor produced by early gustatory epithelia may allow chorda tympani fibers to distinguish gustatory from surrounding epithelium. Finally, multiple chemorepulsive cues likely prevent chorda tympani axons from invading areas prematurely, from exiting the appropriate axonal pathway prematurely, and from innervating nongustatory regions of the epithelium.

One chemorepulsive factor important during both trigeminal and gustatory axon guidance is semaphorin 3A (Sema3A; Rochlin, M. W. and Farbman, A. I., 1998; Rochlin, M. W. *et al.*, 2000), which is expressed in developing tongue (Giger, R. *et al.*, 1996). Sema3A expression decreases medially to laterally across the tongue surface and prevents premature and aberrant growth of trigeminal and gustatory fibers into the tongue mid-region (Rochlin, M. W. and Farbman, A. I., 1998; Rochlin, M. W. *et al.*, 2000). In addition, as geniculate fibers near the epithelial surface, Sema3A may prevent premature penetration of the epithelium (Vilbig, R. *et al.*, 2004).

The lingual epithelium also produces chemoattractants (Gross, J. B. *et al.*, 2003; Vilbig, R. *et al.*, 2004). Axons of gustatory neurons isolated from the epibranchial placodes of axolotl are attracted to the pharyngeal endoderm (Gross, J. B. *et al.*, 2003). In addition, tongue explants from rats attract geniculate ganglion axons in culture (Vilbig, R. *et al.*, 2004). The chemoattractive factor emanating from the tongue epithelium has not yet been identified; however, it is probably not a neurotrophin because its chemoattractive properties are not blocked by the addition of high concentrations of neurotrophic factors to the culture media (Vilbig, R. *et al.*, 2004). This unidentified factor may be responsible for encouraging initial gustatory axon growth into the tongue and/or may direct chorda tympani branches to grow toward the dorsal tongue epithelia.

Although neurotrophins are not required to attract gustatory axons to the tongue, *in vitro* and *in vivo* studies support a chemotropic role for neurotrophins in the developing taste system. Growth cones reorient and grow toward a neurotrophin source (Ming, G. *et al.*, 1997; Paves, H. and Saarma, M., 1997; Ming, G. *et al.*, 1999; Tucker, K. L. *et al.*, 2001) and axons of the geniculate ganglion are attracted to beads containing BDNF (Rochlin, M. W. *et al.*, 2006). In the tongue, BDNF is located in gustatory epithelium while the surrounding somatosensory epithelium primarily expresses NT3 (Nosrat, C. A. and Olson, L., 1995; Nosrat, C. A. *et al.*, 1996; Nosrat, C. A., 1998; Fan, L. *et al.*, 2004). Thus, BDNF and NT3 are in the correct locations to direct gustatory fibers to fungiform papillae and somatosensory fibers to nongustatory epithelium. Consistent with these possible roles for BDNF and NT3, the disruption of the normal BDNF expression pattern *in vivo* prevents chorda tympani innervation of fungiform papillae (Ringstedt, T. *et al.*, 1999; Krimm, R. F. *et al.*, 2001; Lopez, G. F. and Krimm, R. F., 2006a). Specifically, overexpression of BDNF throughout the lingual epithelium, under the control of a keratin 14

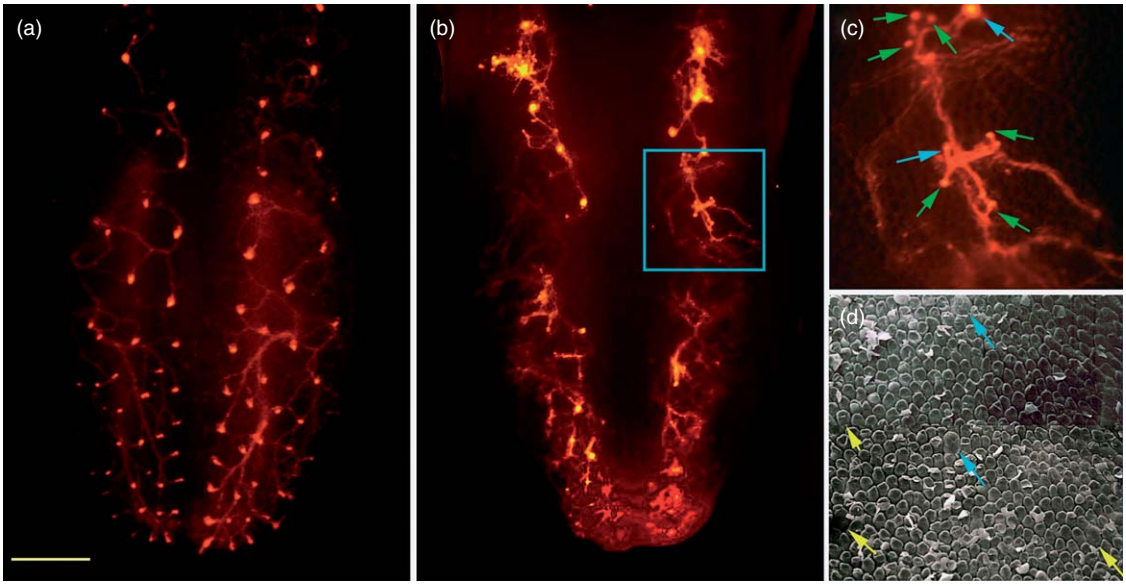

Figure 5 Innervation patterns are disrupted in BDNF-OE mice (b) compared with wild type mice (a). Fibers from the chorda tympani branch as they near the tongue surface in wild type mice (a) and innervate specific regions of the epithelium. In BDNF-OE mice (b), many thin processes are present near the epithelial surface; however, most fail to innervate fungiform papillae. The apparent disorganization of gustatory innervation can be seen more clearly in higher magnification of the tongue mid-region (c) along with scanning electron microscopy of the same region (d). While some of fungiform papillae appear to be innervated (blue arrows in c,d), some regions of the tongue epithelium are innervated by gustatory fibers even though no fungiform papillae are near by (green arrows in c). In addition, some fungiform papillae clearly remain uninnervated (yellow arrows in d). Scale bar in (a) = 500 μm and applies to (a) and (b).

promoter, disrupts the initial innervation of fungiform papillae and alters the normal morphology of gustatory sensory neurons (Figure 5; Krimm, R. F. *et al.*, 2001; Lopez, G. F. and Krimm, R. F., 2006a). BDNF overexpression also increases branching and attracts gustatory innervation to inappropriate regions of the taste epithelium. Finally, BDNF overexpression in both muscle and gustatory neurons disrupts chorda tympani target innervation (Ringstedt, T. *et al.*, 1999). Importantly, removal of functional BDNF also disrupts normal targeting (Lopez, G. F. *et al.*, 2006). In $BDNF^{-/-}$ mice, geniculate axons enter the tongue and grow toward the lingual epithelium normally, but once they near the epithelial surface, they grow wildly in the lamina propria and fail to penetrate the developing gustatory epithelia. Taken together, these findings indicate hat the chemoattractant properties of BDNF allow chorda tympani fibers to select and penetrate fungiform placodes as their appropriate target. It is still not clear whether NT3 is required to direct somatosensory afferents toward the nongustatory lingual epithelium, but NT3 expression patterns are consistent ith this possibility (Nosrat, C. A. and Olson, L., 1998).

4.06.6.3 Development of Projections of Gustatory Neurons to the Central Nervous System

The central axons of all cranial ganglion sensory neurons, including those of gustatory ganglia, project to the hindbrain. In axolotl, projections from early forming ganglia reach both peripheral and central targets earlier than later forming ganglia (Fritzsch, B. *et al.*, 2005). Each cranial ganglion forms its central and peripheral projections simultaneously, ruling out the possibility that innervation of peripheral targets directs central innervation and vice versa. Instead, the central and peripheral targets for these ganglia appear to be selected as the ganglia develop, with more ventrally located ganglia developing first and innervating central and peripheral targets that form early. More dorsally located ganglia develop later and innervate peripheral and central targets that develop later, thus suggesting that early molecular cues for ganglion differentiation may also influence the selection of central targets.

In rat CNS, geniculate ganglion axons begin to invade the first central nucleus of the gustatory system in the hindbrain, the nucleus of the solitary tract

(NTS), at E15 (Zhang, L. L. and Ashwell, K. W., 2001), the same age that peripheral fiber bundles arrive at fungiform papillae (Farbman, A. I. and Mbiene, J.-P., 1991). Thus, similar to axolotl, rat CNS projections from gustatory ganglia develop at the same time as peripheral projections. Consequently, peripheral connections with fungiform papillae probably do not control CNS targeting. Rather, as in axolotl, molecular cues for timing ganglia differentiation may also direct CNS targeting. Consistent with this idea, in mammals, the same transcription factor (e.g., Phox2b) regulates the development of geniculate and petrosal ganglia and their CNS target, the NTS, thus coordinating visceral sensory circuitry (Dauger, S. *et al.*, 2003).

Centrally projecting taste afferents find their way to the hindbrain by following the path of migrating neuroglial neural crest from the hindbrain (Begbie, J. and Graham, A., 2001b). When the neural crest is ablated prior to migration, gustatory ganglion neurons fail to migrate internally from the epibranchial placodes. Central processes of these neurons form aberrant connections, frequently with adjacent ganglia, and fail to project toward the hindbrain. Thus, early developmental events such as the timing of ganglion differentiation, transcription factors, and migrating neural crest cells function together to regulate the initial growth of gustatory projections to the NTS.

4.06.6.4 Survival and Maintenance of Gustatory Neurons and Taste Buds

In addition to their demonstrated role in targeting of gustatory afferents, neurotrophins are also important for gustatory neuron survival. The traditional view of neurotrophic function is that sensory neuron targets regulate the number of surviving neurons by secreting limited amounts of neurotrophic compounds. BDNF may function as an important target-derived factor in the taste system, influencing neuronal survival after initial innervation of gustatory epithelium. BDNF mRNA is expressed in cells of the developing gustatory epithelium and taste buds (Nosrat, C. A. and Olson, L., 1995; Nosrat, C. A. *et al.*, 1996), and BDNF expression begins prior to, and occurs independently of, gustatory innervation (Nosrat, C. A. and Olson, L., 1995; Nosrat, C. A. *et al.*, 2001). The geniculate ganglion also produces BDNF (Schecterson, L. C. and Bothwell, M., 1992), which may influence neuronal survival through an autocrine or paracrine mechanism (Acheson, A. *et al.*, 1995; Acheson, A. and Lindsay, R. M., 1996). The central target of geniculate and petrosal neurons, the NTS, also produces BDNF, which may regulate survival of gustatory neurons (Acheson, A. *et al.*, 1995).

Regardless of its source, BDNF is an important regulator of gustatory neuron number. $BDNF^{-/-}$ mice lose approximately half of their geniculate and nodose/petrosal ganglion neurons during development (Conover, J. C. *et al.*, 1995; Liu, X. *et al.*, 1995; Erickson, J. T. *et al.*, 1996; Liebl, D. J. *et al.*, 1997). Although both of these ganglia innervate taste and nontaste regions, many of the neurons lost in $BDNF^{-/-}$ mice probably innervate taste buds. Taste buds, in turn, require gustatory innervation for their continued maintenance (Hosley, M. A. *et al.*, 1987; Nagato, T. *et al.*, 1995; Sollars, S. I., 2005), and it is well established that fungiform and circumvallate taste buds are lost by birth in $BDNF^{-/-}$ mice (Nosrat, C. A. *et al.*, 1997; Zhang, C. *et al.*, 1997; Cooper, D. and Oakley, B., 1998; Oakley, B. *et al.*, 1998; Mistretta, C. M. *et al.*, 1999; Sun, H. and Oakley, B., 2002). The most likely explanation for these findings is that BDNF produced in either taste papillae, gustatory ganglia, or NTS is required for the survival of gustatory neurons, which in turn maintain taste buds. Therefore, the neurons lost in $BDNF^{-/-}$ mice are most likely gustatory neurons; however, retrograde labeling has not yet been used to determine the number of gustatory neurons that are lost in $BDNF^{-/-}$ mice.

Geniculate neurons are first lost in $BDNF^{-/-}$ mice between E12.5 and E14.5, indicating these neurons are first lost just before or as they innervate gustatory epithelia (Patel, A. V. and Krimm, R. F., 2005). However, geniculate neuron loss continues after E14.5, indicating the BDNF is required to support geniculate neuron survival throughout embryonic development.

BDNF is not the only neurotrophin that regulates taste system development. In addition, NT4 is expressed in tongue, taste buds, and geniculate ganglion neurons (Cho, T. T. and Farbman, A. I., 1999; Farbman, A. I. *et al.*, 2004b; Takeda, M. *et al.*, 2005a), and $NT4^{-/-}$ mice lose approximately half of their geniculate and nodose/petrosal ganglion neurons during development (Conover, J. C. *et al.*, 1995; Liu, X. *et al.*, 1995; Erickson, J. T. *et al.*, 1996). Moreover, double $BDNF^{-/-}/NT4^{-/-}$ null mutants lose $\geq$90% of geniculate and petrosal neurons (Conover, J. C. *et al.*, 1995; Liu, X. *et al.*, 1995; Erickson, J. T. *et al.*, 1996), indicating that NT4- and BDNF-dependent neurons may represent two separate populations. Fungiform papillae are lost by birth in $NT4^{-/-}$ mice (Liebl, D. J. *et al.*, 1999), but circumvallate

taste buds are not, indicating that at least some of the NT4-dependent neurons in the geniculate ganglion are gustatory, while those in the petrosal ganglion are not. In $NT4^{-/-}$ mice, neurons are lost earlier than in $BDNF^{-/-}$ mice before E12.5, which is before target innervation (Patel, A. V. and Krimm, R. F., 2005). Also in $NT4^{-/-}$ mice, there is a separate wave of neuron loss between E14.5 and E16.5, distinct from neuronal loss in $BDNF^{-/-}$ mice. Thus, it is likely that NT4 plays two distinct roles at different stages of geniculate neuron development.

In addition to BDNF and NT4, NT3 may also play a regulatory role in gustatory neuron development. There is an abundance of NT3 in the tongue (Nosrat, C. A. *et al.*, 1996; Nosrat, C. A. and Olson, L., 1998; Fan, L. *et al.*, 2004) and ~45% of geniculate and nodose/petrosal neurons are lost in $NT3^{-/-}$ mice (Liebl, D. J. *et al.*, 1997). Oddly, while no fungiform papillae are lost in $NT3^{-/-}$ mice, double $BDNF^{-/-}/NT3^{-/-}$ null mutants lose more fungiform papillae than $BDNF^{-/-}$ mice (Nosrat, C. A. *et al.*, 2004), suggesting that NT3-supported trigeminal neurons maintain taste buds in the absence of BDNF. Alternatively, NT3 could function in conjunction with BDNF to support gustatory neurons, or NT3 could have a direct, nerve-independent, influence on taste bud maintenance.

The neurotrophins, BDNF and NT4, function via the same receptors, TrkB, a member of the tyrosine kinase family, and p75, a pan-neurotrophin receptor. All mouse geniculate neurons express the TrkB receptor early in development (Yamout, A. *et al.*, 2005). While some geniculate neurons in rat continue to express TrkB postnatally and into adulthood, most express other neurotrophin receptors (Cho, T. T. and Farbman, A. I., 1999; Farbman, A. I. *et al.*, 2004a; 2004b). Expression of neurotrophin receptors in the geniculate ganglion may vary across rodent species; however, more likely, TrkB is downregulated postnatally. Mice lacking TrkB lose geniculate neurons by E12.5 (Fritzsch, B. *et al.*, 1997), and by E13.5, neuronal loss is greater in $TrkB^{-/-}$ mice than in $NT4^{-/-}$ or $BDNF^{-/-}$ mice, indicating that both neurotrophins regulate survival via TrkB. Because most geniculate and nodose/petrosal neurons are lost in $TrkB^{-/-}$ mice, taste buds may not receive gustatory innervation in $TrkB^{-/-}$ mice. Some fungiform taste buds are present at birth in $TrkB^{-/-}$ mice (Fritzsch, B. *et al.*, 1997); however, taste bud number has not been quantified, so how many remain is unclear.

Other factors are also required to maintain gustatory neurons and taste buds. Disruption of dystonin, a molecule important for cytoskeletal organization, causes a loss of petrosal ganglion neurons and a loss of circumvallate taste buds (Ichikawa, H. *et al.*, 2006). Although dystonin regulates neuronal cytoskeletal organization, only some subpopulations of neurons, primarily sensory neurons, are effected by its removal. There is a possible link between dystonin function and neuronal dependence on the neurotrophins NT3 and GDNF, in that the somatosensory neurons that are most sensitive to disruption of dystonin also tend to depend on either NT3 or GDNF for survival (Carlsten, J. A. *et al.*, 2001). Possible roles of NT3 in gustatory neuron development/maintenance have already been discussed. Currently, it is unclear whether GDNF plays a role in gustatory development. GDNF is expressed by the developing tongue (Nosrat, C. A. *et al.*, 1998) and adult taste buds (Takeda, M. *et al.*, 2004; 2005b) and geniculate neurons express GDNF receptors (Yamout, A. *et al.*, 2005). Furthermore, removal of GDNF reduces the number of petrosal ganglion neurons (Erickson, J. T. *et al.*, 1996). Thus a role for GDNF in gustatory system development or maintenance remains likely.

In addition to the known factors, an unidentified factor produced by gustatory neurons acts to maintain taste buds during development and into adulthood (Hosley, M. A. *et al.*, 1987; Oakley, B. *et al.*, 1990; Nagato, T. *et al.*, 1995; Sollars, S. I. *et al.*, 2002; Sollars, S. I., 2005). It is reasonable to hypothesize that this unknown factor is a growth factor, and growth factors typically function via tyrosine kinase receptors. With this possibility in mind, McLaughlin S. K. (2000) amplified both receptor and nonreceptor tyrosine kinases from a cDNA library to identify tyrosine kinases expressed in taste buds. The tyrosine kinase receptors, ErbB1 (the epithelial growth factor receptor, (Egfr)), ErbB2, ErbB3, and c-kit tyrosine kinase receptors are all preferentially expressed in taste buds (McLaughlin, S. K., 2000). ErbB2 typically functions as a coreceptor, but ErbB1 and ErbB3 have ligand-binding abilities. ErbB1/ErbB1 and ErbB1/ErbB2 heterodimers typically bind EGF, TGFα, and amphiregulin. Fungiform papillae and/or taste buds are lost and malformed in mice lacking Egfr/ErbB1 (Miettinen, P. J. *et al.*, 1995; Threadgill, D. W. *et al.*, 1995), but sensory innervation is unaffected (Sun, H. and Oakley, B., 2002). Thus, Egfr/ErbB1 signaling is important for the maintenance of taste buds.

One ligand of this receptor, EGF, is expressed in the tongue where it influences early fungiform placode development (Mistretta, C. M. *et al.*, 2005), indicating that taste bud loss in $ErbB1^{-/-}$ mice could be due to disruption of early placode development. Another

intriguing possibility is that EGF in saliva maintains taste buds and fungiform papillae via ErbB1 (Morris-Wiman, J. *et al.*, 2000). Consistent with this interpretation, taste buds in circumvallate and foliate papillae are unaffected by either mutation of Egfr/ErbB1 or salivary gland removal (Morris-Wiman, J. *et al.*, 2000; Sun, H. and Oakley, B., 2002). Also, the addition of EGF to drinking water rescues the taste bud loss seen with salivary gland removal (Morris-Wiman, J. *et al.*, 2000). Lastly, it is possible that gustatory neurons produce an Erb ligand that is important for taste bud maintenance. This would be consistent with the role of other Erb ligands in the maintenance of sensory receptors (Hippenmeyer, S. *et al.*, 2002). Thus, while Erb receptor ligands may function to maintain taste buds, the exact function and source of these ligands is unclear. Equally elusive is the nature of the factor(s) produced by gustatory neurons that serves to support both taste bud differentiation during development and taste bud maintenance in adulthood.

4.06.7 Postnatal Plasticity in Taste Bud Innervation

Taste buds continue to develop postnatally, to turn over, and to reestablish connections with innervating neurons even into adulthood (Beidler, L. M. and Smallman, R. L., 1965). Changes in peripheral gustatory innervation patterns are related to, and may even regulate, changes in taste bud development. In adult rats, taste bud size is correlated with the number of geniculate ganglion neurons that innervate it (Krimm, R. F. and Hill, D. L., 1998b). This relationship develops over a prolonged period of postnatal development and is not observed until postnatal day 40 (PN40). Between PN10 and PN40, geniculate ganglion cells rearrange their peripheral connections (Krimm, R. F. and Hill, D. L., 2000), withdrawing innervation from certain taste buds, then innervating others. This constant rearrangement of peripheral connectivity does not appear to establish the relationship between taste bud size and geniculate neuron number. That is, individual ganglion neurons do not remove innervation from small taste buds in favor of larger taste buds. Instead, the number of neurons that innervate a given taste bud at PN10 predicts taste bud size at PN40. Thus, the number of neurons innervating a given taste bud is established early in development and taste buds grow to match the number of neurons innervating them.

Taste buds grow between PN10 and PN40 by adding taste cells (Hendricks, S. J. *et al.*, 2004). Taste cells are constantly turning over, undergoing a continuous process of differentiation followed by death (Beidler, L. M. and Smallman, R. L., 1965). Postnatal differences in taste cell proliferation, differentiation, or life span could all increase the number of taste bud cells. The approximate 10-day life span of taste cells appears to remain constant during development (Hendricks, S. J. *et al.*, 2004) as does the proliferation rate of basal cells. However, the rate of taste cell addition accelerates. It is unclear what factor(s) controls the addition of new taste cells. Because taste buds increase in size in proportion to the amount of neural innervation they receive (Krimm, R. F. and Hill, D. L., 2000), the critical factor may be neuronal. Alternatively, factor(s) produced in fungiform papillae could regulate both the rate of taste cell addition and the number of neurons innervating the taste bud.

The number of geniculate neurons that typically innervate a fungiform taste bud varies considerably across rodent species. Rat taste buds are innervated by 3–14 ganglion neurons (Krimm, R. F. and Hill, D. L., 1998a; Shuler, M. G. *et al.*, 2004) while mouse taste buds are innervated by substantially fewer (2–7) (Zaidi, F. N. and Whitehead, M. C., 2006). Hamster fungiform taste buds are innervated by many more geniculate neurons (5–35) than either rat or mouse taste buds (Whitehead, M. C. *et al.*, 1999; Zaidi, F. N. and Whitehead, M. C., 2006). Differences in peripheral branching characteristics of ganglion cells (Zaidi, F. N. and Whitehead, M. C., 2006), rather than differences in the ratio of fungiform taste buds to geniculate neurons, appear to account for species variation. That is, geniculate neurons branch more and innervate more taste buds in hamsters than in mice (Zaidi, F. N. and Whitehead, M. C., 2006). It is unclear whether postnatal plasticity also diverges across species as a reflection of geniculate neuron branching.

4.06.8 Plasticity of Central Taste Connections

As discussed earlier, initial projection of gustatory axons to the NTS is dictated by early developmental cues, whereas further refinement occurs over a protracted developmental period after birth. The combined terminal field of the chorda tympani and the greater superficial petrosal (GSP) afferents steadily increases between PN7 and PN25 (Lasiter, P. S. and Bulcourf, B. B., 1995), illustrating that terminal field development is not complete until late postnatal

stages. The terminal field of the chorda tympani nerve increases until PN15, then decreases in size (Sollars, S. I. *et al*., 2006) before becoming adult-like at PN35. Postsynaptic neurons in the gustatory NTS also undergo remodeling between PN22 and PN28 (Liu, Y. S. *et al*., 2000). For example, dendritic fields of salt-sensitive geniculate ganglion neurons decrease during this postnatal period. Because NTS connections are refined during late postnatal development, remodeling of these connections may be influenced by sensory experiences in the taste system.

In most sensory systems, including the taste system, blocking normal sensory experiences alters the development of central connections (Hubel, D. H. and Wiesel, T. N., 1970; Cummings, D. M. and Brunjes, P. C., 1997; Fox, K. *et al*., 2002). Similarly, fungiform papillae/taste bud damage at PN2 stunts the terminal field expansion of the combined chorda tympani/GSP nerves in the NTS (Lasiter, P. L. and Kachele, D. L., 1990). The underlying mechanisms are unclear but may include injury-induced expression of numerous growth and/or immune factors or the loss of primary sensory afferents.

Developmental sodium restriction also influences later sensory experiences. Maternal sodium restriction during embryonic development specifically blocks postnatal development of chorda tympani nerve responses to sodium salts (Hill, D. L. and Przekop, P. R., 1988) and substantially alters the CNS projections of gustatory neurons. Chorda tympani and glossopharyngeal terminal fields within the rostral NTS are enlarged (King, C. T. and Hill, D. L., 1991; Krimm, R. F. and Hill, D. L., 1997; May, O. L. and Hill, D. L., 2006; Sollars, S. I. *et al*., 2006) because connections are not refined and eliminated between PN25 and PN35, resulting in adult projections with an early developmental morphology (Sollars, S. I. *et al*., 2006). Interestingly, unlike for the chorda tympani nerve, sodium responses in the GSP nerve are unaffected by sodium deprivation as is the size of the terminal field (Sollars, S. I. and Hill, D. L., 2000; May, O. L. and Hill, D. L., 2006). Alterations due to sodium restriction are not limited to the terminal fields of the affected primary afferents; postsynaptic neurons are also affected. Dendritic arbors of putative projection neurons in the gustatory NTS are longer in sodium-restricted rats than in controls (King, C. T. and Hill, D. L., 1993). The mechanisms through which sodium deprivation influences gustatory CNS development are not yet clear. Probably, the failure of the chorda tympani nerve to develop sodium sensitivity reduces total postnatal chorda tympani activity, thus preventing postnatal refinement of the terminal field.

4.06.9 Conclusion

The general organization of the taste system is conserved across vertebrate species, from fish to humans: bipolar sensory neurons of the VII, IX, and X cranial ganglia convey taste information from aggregates of spindle-shaped cells, taste buds, located in the oral and pharyngeal epithelia to the first relay nucleus, the NTS, in the hindbrain. We propose that this conservation of anatomy is reflected in a conserved and basic plan for the development of elements of the taste system. Taste bud progenitors arise from the local epithelium and are induced and patterned via epithelium-intrinsic intercellular communication. While little is known specifically about the development of the NTS, it is clear that these cells arise from the hindbrain in all vertebrates. Gustatory neurons arise from epibranchial placodes and pathfind simultaneously to innervate both peripheral and central targets, allowing formation of a functional taste system.

Of course, there are variations in this theme, when one examines the details of development within several species. Chief among the differences encountered is the role of innervation in the differentiation of taste buds. In amphibians, taste buds differentiate fully in the complete absence of nerves, while full cytodifferentiation likely depends upon innervation in rodents. Additionally, the development of taste buds in many species, including mammals, is interwoven with the development of specialized epithelial structures, such as taste papillae. Thus, the interconnectedness of buds and papillae may obscure our ability to readily detect commonalities in taste organ developmental mechanisms across species.

However, by continuing to explore taste system development in a number of vertebrates, perhaps expanding to employ additional developmental models, such as zebrafish and chick, we will gain a clearer view of the basic mechanisms underlying development of this key sensory system.

4.07.1 Introduction

Since the nineteenth century, sweet-tasting candies have been the first purchase children make with their own money (Woloson, W. A., 2002). The liking for all that tastes sweet is universal and a hallmark of development. Although strong evidence is lacking, it has been suggested that such preferences evolved to solve a basic nutritional problem of attracting children to sources of high energy during periods of maximal growth (Simmen, B. and Hladik, C. M., 1998; Beauchamp, G. K., 1999; Coldwell, S. E. and Oswald, T. K., 2004).

In this essay, the scientific literature that documents the innate and heightened preferences that children have for sweet-tasting foods and beverages when compared to adults will be reviewed. This review serves as a foundation for a discussion on the pain-reducing properties of sugars which, along with heightened sweet preferences, may be an identifying feature of childhood.

4.07.2 Ontogeny of Sweet Preferences

4.07.2.1 Fetal Life and Infancy

The preference for sweet tastes is present early in ontogeny and remarkably well conserved phylogenetically (Steiner, J. E. *et al.*, 2001). Although each measure has its limitations, the convergence of findings from the scientific literature suggests that from birth, infants are quite sensitive to and prefer sweet tastes. This ability to detect sweet tastes and, in turn, the efficacy of sweets to modulate a variety of behaviors may be evidenced as early as fetal life. It should be emphasized that although the response of human fetuses to sweet taste has never been directly investigated, indirect evidence from albeit methodologically flawed studies (see Mistretta, C. M. and Bradley, R. M., 1977), suggests that that prenatal monitoring of taste stimuli dissolved in amniotic fluid is possible during late gestation. That is, two studies reported increased fetal swallowing following the injection of sweet stimuli such as saccharin (De Snoo, K., 1937; Liley, A. W., 1972) into the amniotic fluid of pregnant women and decrease swallowing following the injection of a bitter-tasting substance (Liley, A. W., 1972).

Stronger evidence that the fetus can respond to taste stimuli comes from research on premature infants. To overcome methodological limitations and because premature infants often have immature suck–swallow coordination, innovative methods were developed that avoided the risk of fluid aspiration by embedding the taste substance in a nipple-shaped gelatin medium that released small amounts of the sweet substance when mouthed or sucked. Infants born preterm and tested between 33 and 40 weeks postconception produced stronger and more frequent sucking responses when offered the sucrose-sweetened nipple compared with a latex nipple (Maone, T. R. *et al.*, 1990).

After birth, the liking for sweet tastes is unequivocal. Newborns are sweet connoisseurs. They respond to even dilute sweet tastes, differentiate varying degrees of sweetness, and will consume more of a sugar solution when compared to water (Desor, J. A.

et al., 1973; Nowlis, G. H. and Kessen, W., 1976). When a sweet solution is placed in the oral cavity, the infant's face relaxes, resembling an expression of satisfaction which may be followed by a smile (Steiner, J. E., 1977; Rosenstein, D. and Oster, H., 1988). That the positive facial expressions elicited by sweet-tasting sugars are reflexlike is supported by the finding that single response components, such as tongue movements, can be reliably elicited in newborns by sweet tastes in a concentration-dependent manner (e.g., Nowlis, G. H. and Kessen, W., 1976; Weiffenbach, J. M., 1977). Moreover, neonates born with severe developmental malformations of the central nervous system (e.g., anencephalic infants) react to sweet tastes, as well as other tastants, like normal, term infants (Steiner, J. E., 1977).

Newborns also respond to sweet stimulation with changes in autonomic response (e.g., Crook, C. K. and Lipsitt, L. P., 1976; Lipsitt, L. P. *et al.*, 1976; Lipsitt, L. P., 1977; Haouari, N. *et al.*, 1995; Rao, M. *et al.*, 1997; Blass, E. M. and Watt, L. B., 1999), but the behavioral state of the infant modifies the direction of the change. For example, heart rate increased proportionally when increasing concentrations of sucrose were placed in the mouths of nonagitated infants (Ashmead, D. H. *et al.*, 1980). Conversely, heart rate decreased when sweet tastes were introduced to infants who were agitated, resulting in overall calmness (e.g., Blass, E. M. and Watt, L. B., 1999). Furthermore, electroencephalographic recordings of 2–3-day-old newborns revealed that infants respond to sucrose administration with an asymmetry of brain electrical activity, a response which is usually associated with hedonically positive emotional reactions or approach behavior (Fox, N. A. and Davidson, R. J., 1986).

4.07.2.2 Childhood and Adolescence

The preference for sweet taste is universal and evident among children around the world (e.g., Brazil (Tomita, N. E. *et al.*, 1999); France (Bellisle, F. *et al.*, 1990); Iraq (Jamel, H. A. *et al.*, 1997); Israel (Steiner, J. E. *et al.*, 1984); Mexico (Vazquez, M. *et al.*, 1982); The Netherlands (De Graaf, C. and Zandstra, E. H., 1999); and North America (Desor, J. A. *et al.*, 1975; Beauchamp, G. K. and Cowart, B. J., 1987; Liem, D. G. and Mennella, J. A., 2002). Both cross-sectional and longitudinal studies revealed that the preference for sweets remains heightened throughout childhood (Beauchamp, G. K. and Moran, M., 1984; Mennella, J. A. *et al.*, 2005; Pepino, M. Y. and Mennella, J. A., 2005a) and early adolescence (Desor, J. A. *et al.*, 1975) and declines to adult levels during late adolescence (Desor, J. A. and Beauchamp, G. K., 1987).

The level of sucrose that children prefer, as measured in the laboratory, is significantly related to children's preferences for sweet-tasting foods such as cereals (Liem, D. G. and Mennella, J. A., 2002; Mennella, J. A. *et al.*, 2005) and beverages (Olson, C. M. and Gemmill, K. P., 1981; Mennella, J. A. *et al.*, 2005). Sweet taste can clearly drive consumption such that adding sugar to beverages such as Kool Aid™ (Beauchamp, G. K. and Moran, M., 1984) and solid foods such as spaghetti (Filer, L. J., 1978), ricotta, and jicama (Sullivan, S. A. and Birch, L. L., 1990) increased both liking and acceptance by children.

What causes the developmental shift in sweet preferences and consumption between childhood and adulthood remains a mystery, but this age-related decline in sweet preference has been observed in other mammals (Wurtman, J. J. and Wurtman, R. J., 1979; Bertino, M. and Wehmer, F., 1981; Marlin, N. A., 1983). Two hypotheses, not mutually exclusive, are presented here. First, children may be less sensitive to sweet tastes, thereby requiring larger amounts of sugars to obtain optimal sweetness. However, there is no strong evidence that the heightened sweet preference evidenced during infancy and childhood is due to decreased sensitivity to sweet tastes (see Cowart, B. J., 1981 for review). Whereas some investigators may report that children are more sensitive than adults when small regions of the anterior tongue are stimulated with sucrose (Stein, N. *et al.*, 1994), others found that taste sensitivity during childhood does not differ from that during adulthood (Cowart, B. J., 1981). Second, the heightened sweet preferences early in life may be linked to the growing child's need for calories (Drewnowski, A., 2000). Recent findings support this hypothesis. In brief, 11–15-year-old children were divided into sweet likers and dislikers based on their sucrose preferences (Coldwell, S. E. and Oswald, T. K., 2004). Although there were no differences between these two groups in measures such as sucrose detection thresholds, age, body mass index, percent of body fat, and pubertal development, growth rate was significantly lower in dislikers when compared to sweet likers suggesting that the age-related decline in sucrose preferences may be related to the cessation of growth.

4.07.2.3 Early Experiences and Contextual Learning about Sweets

Although the scientific evidence supports the hypothesis that sweet taste liking is innate and present at birth, if not earlier, the degree to which early experiences alter or modulate the development of sweet preferences later in life is largely unknown. Longitudinal studies revealed that babies who were routinely fed sweetened water (e.g., water sweetened with table sugar, Karo syrup or honey) during the first months of life exhibited a greater preference for sweetened water when tested at 6 months (Beauchamp, G. K. and Moran, M., 1982) and then again at 2 years of age (Beauchamp, G. K. and Moran, M., 1984) when compared to those who had little or no experience with sweetened water. Similarly, a more recent cross-sectional study on 6–10-year-old children revealed that such feeding practices may have longer-term effects on the preference for sweetened water than previously realized (Pepino, M. Y. and Mennella, J. A., 2005a).

Whether early experience with sweetened water modifies overall liking for sweetened foods is less uncertain. In fact, there is no compelling data suggesting that repeated exposure to sugar water results in a generalized heightened hedonic response to sweetness (Beauchamp, G. K. and Moran, M., 1984). Moreover, 4–7-year-old children whose mothers reported adding sugar to their foods on a routine basis were significantly more likely to prefer apple juices with added sugar and cereals with higher sugar contents than similar age children whose mothers reported never adding sugar to the foods at home (Liem, D. G. and Mennella, J. A., 2002). These data support the hypothesis that the context in which the taste experience occurred is an important factor and through familiarization, children develop a sense of what should, or should not, taste sweet (Beauchamp, G. K. and Cowart, B. J., 1985).

4.07.3 Pain-Reducing Properties of Sweet Tastes

4.07.3.1 Infancy

The pioneering research of Elliott Blass, Ronald Barr, and their colleagues revealed, more than a decade ago, that tasting a sweet substance modified crying behaviors and certain physiological responses in infants. A small amount of a sweet solution placed on the tongue of a crying newborn exerts a rapid, calming effect that persists for several minutes (Blass, E. M. and Hoffmeyer, L. B., 1991; Barr, R. G. *et al.*, 1994). Sweet tastes can also blunt expressions of pain, and calm both preterm and full-term infants who have been subjected to painful events such as heel stick or circumcision (see Stevens, B. *et al.*, 2004 for review). That sucrose attenuated a negative electroencephalographic response to a painful procedure (Fernandez, M. *et al.*, 2003) suggests that sucrose blocks pain afferents which, in turn, diminish stress and cardiac changes. Because noncaloric sweet substances such as aspartame mimic the calming effects of sucrose (Barr, R. G. *et al.*, 1999; Bucher, H. U. *et al.*, 2000) and because the administration of sucrose by direct stomach loading is not effective (Ramenghi, L. A. *et al.*, 1999), afferent signals from the mouth, rather than gastric or metabolic changes, appear to be responsible for the analgesic properties of sweet tastes.

Other flavors and orosensory components also reduce pain in infants and may act synergistically with sweet tastes. These include the flavor of mother's milk (Upadhyay, A. *et al.*, 2004) and some of its constituents (i.e., fat, protein; Blass, E. M., 1997). Orotactile stimulation from a pacifier (Blass, E. M. and Hoffmeyer, L. B., 1991; Carbajal, R. *et al.*, 1999), maternal skin-to-skin contact (Gray, L. *et al.*, 2000), or being held before and during the painful procedure (Gormally, S. *et al.*, 2001) also produce the analgesic effect, but the effects are transient when compared to when sweet taste is in the oral cavity (Smith, B. A. *et al.*, 1990). Although the use of sterile sugar water to reduce pain in infants is now routine practice in several hospital nurseries because of its natural simplicity, viability and efficacy (Anand, K. J. S., 2001), we caution that more research is needed to determine sweet taste's efficacy in reducing pain after repeated administrations (Stevens, B. *et al.*, 2004).

4.07.3.2 Childhood

The ability of sweet tastes to reduce pain continues during childhood as evidenced by the finding that the presence of sucrose, but not water, in the oral cavity delayed 8–11-year-old children's reporting of pain onset when undergoing a cold-induced pain stimulus test (Miller, A. *et al.*, 1994; Pepino, M. Y. and Mennella, J. A., 2005b). Sucrose's efficacy in reducing pain is related to the hedonic value of sweet taste for the child (Pepino, M. Y. and Mennella, J. A., 2005b). The more children like

sucrose, the better it works in increasing pain tolerance.

Less certain is whether sweet taste continues to be an analgesic during adulthood. While some studies suggested no effects (Miller, A. *et al*., 1994; Mercer, M. E. and Holder, M. D., 1997), others reported increased tolerance to mechanical pain following consumption of palatable sweet food in women but not in men (Blass, E. *et al*., 1987; Mercer, M. E. and Holder, M. D., 1997). From these observations, it can be postulated that if the analgesic response to intraoral sucrose is present during adulthood, it is less robust than that during childhood. The absence or diminution of an analgesic response to sucrose in adults is apparently not due to the lowered sucrose preference observed in adults overall (Miller, A. *et al*., 1994) and is consistent with animal model studies that revealed that sweet-induced analgesia progressively declines during development and is absent by the third week of life in rats (Anseloni, V. C. *et al*., 2002).

4.07.4 Concluding Remarks

The research discussed herein revealed that, as a group, children prefer significantly higher concentrations of sugars in foods and liquids than do adults. Nevertheless, there are striking individual and group differences in the levels of sweetness preferred (Desor, J. A. *et al*., 1975; Beauchamp, G. K. and Moran, M., 1982; Pepino, M. Y. and Mennella, J. A., 2005a). The recent identification of some taste receptor genes (e.g., Drayna, D. *et al*., 2003; Kim, U. K. *et al*., 2003) has enabled us to explore the contribution of genetic variation (see McDaniel A. H. and Reed D. R., 2004). Alleles of the bitter-taste receptor *TAS2R38* gene explained much of the phenotypic variation in the sensitivity to the bitter compound, propylthiouracil, and partially explained individual differences in children's sweet preferences (Mennella, J. A. *et al*., 2005; see also Keller, K. L. and Tepper, B. J., 2004). The future promises more research on how variation in other taste receptor genes, particularly those involved in sweet taste perception, contribute to individual differences in preferences and food habits. More knowledge about the factors that contribute to preferences for sweet-tasting foods and beverages in children, a generation who will struggle with obesity and diabetes, may suggest population-based strategies to overcome diet-induced disease and promote healthy eating habits.

Glossary

allodynia A painful response to a previously non-painful or subthreshold stimulus. Typically occurs after tissue injury and/or inflammation.

hyperalgesia A state characterized by enhanced sensation of pain. Typically occurs after tissue injury and/or inflammation.

mid-collicular transection A surgical procedure used to sever connections between the forebrain and the hindbrain.

von Frey filaments Filaments of various bending forces used to measure responses to mechanical cutaneous stimulation.

4.08.1 Taste Analgesia in Human Infants

Decades of studies have reported the analgesic and calming effects following intraoral infusion of sweet tastants (sucrose, glucose, fructose, aspartame), mother's milk, commercial formula, protein (provomin), fat (coconut, corn, and soy oil), and carbohydrates (polycose) on human infants (Blass, E. M. and Smith, B. A., 1992; Blass, E. M., 1997a; 1997c; Graillon, A. *et al.*, 1997; Blass, E. M. and Miller, L. W., 2001; Akman, I. *et al.*, 2002). Surprisingly, neither lactose nor colostrum has proven to produce analgesic or calming effects (Blass, E. M. and Smith, B. A., 1992; Blass, E. M., 1997a; 1997c; Blass, E. M. and Miller, L. W., 2001). Instead, the most potent taste analgesia is that triggered by sucrose.

The effects of sucrose have been well characterized in human infants. Analgesic and calming effects of taste analgesia are immediate and endure at least 5 min after sucrose termination (Blass, E. M. *et al.*, 1989; Smith, B. A. *et al.*, 1990; Blass, E. M. and Shah, A., 1995). When delivered repetitively (up to three times daily) over a 7-day period, there appears to be little or no tolerance to the analgesic effects of intraoral sucrose (Johnston, C. C. *et al.*, 2002). Intraoral infusion of microliter volumes (100–200 µl) of sucrose over a dose-range of 12–50% produce a flat dose–response relationship (Blass, E. M. *et al.*, 1989; Blass, E. M., 1997b; Overgaard, C. and Knudsen, A., 1999; Smith, B. A. *et al.*, 1990; Blass, E. M. and Hoffmeyer, L. B., 1991; Blass, E. M. and Smith, B. A., 1992).

Sucrose markedly diminishes crying in response to painful standard hospital procedures such as circumcision or blood collection via heel prick (Blass, E. M. and Hoffmeyer, L. B., 1991; Kaufman, G. E. *et al.*, 2002). In those studies, crying, grimacing, and heart rate have been the main assessments of nociception and calming in human newborns. The use of sucrose-coated pacifiers is currently recommended as a behavioral approach in the guidelines for managing pain in human newborns (Anand, K. J., 2001). However, despite the well-documented analgesic effects of

sucrose, a clinically relevant question remains open for investigation: does repetitive administration of sucrose, especially in a neonatal intensive care unit (NICU) preterm infant, have long-term developmental consequences? A study by Johnston C. C. *et al.* (2002) reported that infants receiving intraoral sucrose up to three times daily for 1 week exhibited subsequent impairments in motor development and vigor. The cause of these deficits is unclear, but it is possible that the withdrawal of sucrose may render the infant more susceptible to subsequent pain.

Both preterm (Taddio, A. *et al.*, 2003) and full-term human infants of either cesarean section or vaginal deliveries readily exhibit analgesic and calming effects of sweet tastants. The age range of full term in those studies varied from few hours after birth (Blass, E. M. and Miller, L. W., 2001; Gray, L. *et al.*, 2002) to 2–6-week-old infants (Barr, R. G., *et al.*, 1994; Zeifman, D. *et al.*, 1996). Although rat studies have already unveiled the age-dependency of sucrose-induced analgesia, the age-dependency in human infants remains unclear. One major difference is that sucrose is effective in preterm human newborns, whereas in rats sucrose effects emerge between postnatal (P) day 2 and 3 (Anseloni, V. C. *et al.*, 2002). While the human developmental period over which intraoral sucrose is analgesic has not been systemically studied, it appears to be analgesic in 5–10-year-old children but not adults (Pepino, M. Y. and Mennella, J. A., 2005). Interestingly, this same study showed that analgesia elicited by sucrose correlates with sweet preferences in 5–10-year-old children but not adults. The more the children liked sucrose, the higher its analgesic efficacy. Therefore, the hedonic value of sucrose is reported to be a major component in triggering sucrose effects. It is unknown if there are gender-based differences in taste analgesia in human infants.

In agreement with animal studies discussed below, there is evidence that taste analgesia in human infants is mediated by central opioid mechanisms. Blass E. M. and Ciaramitaro V. (1994) reported that babies born to women who were maintained on methadone during pregnancy did not quiet to the taste of sucrose. This suggests an opioid mediation in the calming, and perhaps the analgesic, effects elicited by intraoral tastants. Taddio A. *et al.* (2003) reported that intraoral administration of sucrose in preterm infants does not lead to an increase in serum β-endorphin concentrations. However, synaptic release of opioid in the central nervous system (CNS) may not translate to increases in the periphery.

4.08.2 Taste Analgesia in Rodents

4.08.2.1 General Properties

Studies in rodents have revealed remarkable similarities of the properties of taste analgesia to those in human infants. As in human infants, intraoral infusion (20–140 µl) of dairy milk or half-and-half produces analgesia in P0 or P10 rats (Blass, E. M. *et al.*, 1991; Blass, E. M., 1997c). The analgesia develops rapidly ($\leq$15 s) and persists for 0.5 min to at least 4 min after termination of infusion (Blass, E. M. *et al.*, 1991; Blass, E. M., 1997c). Milk infusions also reduced ultrasonic vocalizations, similar to its quieting effect in human infants (Blass, E. M. and Fitzgerald, E., 1988). Similar analgesic and quieting effects lasting up to 5 min were obtained by infusion of polycose or corn oil (Shide, D. J. and Blass, E. M., 1989).

Intraoral infusion (0.18 ml) of several sugars present in human and rat mother's milk were also shown to be analgesic in P10 rat pups (Blass, E. M. and Shide, D. J., 1994). Infusion of 0.22 M fructose, sucrose, or glucose reduced spontaneous ultrasonic vocalizations and increased paw withdrawal latencies to a conductive thermal stimulus. By contrast, lactose was ineffective. The rank-order of potencies was sucrose > glucose > fructose, paralleling findings in human infants. Testing of additional sugar concentrations (0.44 and 0.66 M) produced a flat dose–response relationship; that is, no additional effects were observed with higher concentrations. The reason for the flat dose–response function is unclear. Behavioral and electrophysiological studies demonstrate graded responses to these sugars over this concentration range in juvenile rodents. In P14–P20 hamsters, graded responses of the chorda tympani nerve are observed in response to sugars from 0.2 to 0.6 M, although these responses are of smaller amplitude than in adult animals (Hill, D. L., 1988). It is possible that the analgesic mechanisms (e.g., opioid release) activated by the sugars are saturated (i.e., ceiling effect) at 0.2 M and that a graded analgesic effect might be observed only with lower concentrations. Hill D. L. (1988) also reported that the chorda tympani responses to lactose (0.2–0.5 M) were essentially similar to those of fructose and glucose at identical concentrations. Extrapolating to rats, it is thus unclear why fructose and glucose produce analgesia, while lactose does not. One possibility is that central neural responses to lactose may be considerably less than the other sugars. Unfortunately, there is a relative paucity of information on the

development of central gustatory neuronal responses to sugars during early postnatal development in rats.

Are the calming and analgesic effects of intraoral infusion explained by mechanical, somatosensory stimulation of tastant infusion? A number of studies have addressed this question, finding that intraoral infusion of distilled water, saline, or other salt stimuli do not reduce vocalizations and do not produce analgesia (Blass, E. M. *et al.*, 1987; Shide, D. J. and Blass, E. M., 1989; Blass, E. M. *et al.*, 1991; Blass, E. M. and Shide, D. J., 1994; Ren, K. *et al.*, 1997; Anseloni, V. C. *et al.*, 2002; 2005). Thus, the effects of intraoral infusion are not due to somatosensory stimulation from the cannula or fluid movement in the oral cavity, nor are they due to gustatory stimulation of other taste qualities (i.e., salt).

4.08.2.2 Oral Cavity versus Postingestional/Absorptive Mechanism?

An important question is if the quieting and analgesic effects of intraoral sucrose are mediated by stimulation of taste receptors in the oral cavity or to postingestional or absorptive mechanisms? The rapid onset (i.e., within seconds) of the effects of intraoral tastants suggest that they are triggered by oral cavity taste receptors. The contribution of postingestional mechanisms has not been directly examined in animal studies. However, this question was addressed in human infants. Ramenghi L. A. *et al.* (1999) found that while intraoral sucrose reduced crying and behavioral responses indicative of pain following heel lancing, direct stomach loading via a nasogastric tube was without effect. This suggests that stimulation of taste buds in the oral cavity by sucrose is necessary to induce analgesia.

Given that taste analgesia is due to stimulation of taste receptors in the oral cavity, it is of interest to determine which of the various taste-related cranial nerve branches are involved. Taste receptors are topographically distributed throughout the oral cavity and are innervated by three cranial nerves. The chorda tympani and the greater superficial petrosal branches of the facial nerve (VII) innervate the taste receptors of the anterior tongue and palate, respectively. In rats, receptors responsive to sweet stimuli are located primarily on the palate, consistent with observations that greater petrosal nerve fibers are more responsive to sugars than chorda tympani fibers. Taste receptors in the circumvallate and foliate papillae on the posterior tongue are innervated by the lingual branch of the glossopharyngeal nerve (IX), and those in the oropharynx are innervated by superior laryngeal branch of the vagus nerve (X). Gustatory fibers of VII, IX, and X terminate in a rostral–caudal sequence in the rostral, gustatory portion of the nucleus tractus solitarius (rNTS; reviewed in Travers, S. P., 1993). Unfortunately, the contribution of these cranial nerves to taste analgesia has not been investigated. Additional studies are needed to clarify the roles of the gustatory cranial nerves in taste analgesia.

4.08.2.3 Neurochemical Mechanisms – Opioid Mediation

A number of rodent studies have investigated the neurochemical mechanisms underlying taste analgesia. The effects of oral sucrose are similar to those of opioid narcotics such as morphine. Morphine is analgesic, calming, and decreases vocalizations. Blass E. M. *et al.* (1991) reported that the analgesic effect of a single 20 µl intraoral bolus of milk was comparable in magnitude to that elicited by systemic injection of a moderate dose of the morphine ($0.125\ mg\ kg^{-1}$). Other studies showed that the analgesic and quieting effects of intraoral milk and sugars were blocked by systemic injections of the nonselective opioid receptor antagonists naloxone or naltrexone (Blass, E. M. *et al.*, 1987; Blass, E. M. and Fitzgerald, E., 1988; Shide, D. J. and Blass, E. M., 1989; Blass, E. M. *et al.*, 1991). Taken together, these findings demonstrate that the calming and analgesic effects of intraoral fats and sugars are mediated by release of endogenous opioids.

Interestingly, additional studies showed that calming effects of intraoral tastants may also involve the gastrointestinal peptide, cholecystokinin (CCK). Calming effects, as measured by reductions in ultrasonic vocalizations, are elicited by systemic injection of CCK (Weller, A. and Blass, E. M., 1988). In the same study, CCK had no effect on pain thresholds. CCK receptor antagonists were subsequently found to block the calming effects of intraoral milk or corn oil, but not milk (Blass, E. M. and Shide, D. J., 1993; Weller, A. and Gispan, I. H., 2000). These studies indicate that the calming, but not the analgesic, effects of intraoral tastant involve a CCK component.

4.08.3 Outstanding Issues and Recent Developments

Sucrose-induced analgesia in rats and humans develops within seconds, lasts for minutes, is prevented by

systemic injection of opiate receptor antagonists, and is compromised in human infants born to opiate-dependent mothers. Thus, the mechanisms appear to be remarkably well conserved phylogenetically and involve central opioid systems. A number of critical questions about taste analgesia remain unanswered. The rodent work summarized above was confined to the early postnatal period (P0–P10). Does taste analgesia exhibit a critical period in which intraoral tastants are effective? In other words, is this phenomenon developmentally transient? The pain-relieving effects of intraoral tastants were assayed in acute pain tests using primarily noxious thermal stimuli. Are intraoral tastant equally effective for other types of nociceptive stimuli, such as mechanical stimuli? Persistent inflammatory pain is a major consequence of tissue injury. Are intraoral tastants effective in attenuating hyperalgesia and allodynia associated with tissue injury? The neural circuits by which taste stimuli engage central opioid analgesic mechanisms are not known. The remainder of this chapter summarizes recent studies from our laboratories that have begun to address these questions.

4.08.3.1 Ontogeny of Taste-Analgesia and Efficacy for Inflammatory Pain

We investigated the effects of intraoral sucrose (7.5%) on nocifensive withdrawal responses to thermal and mechanical stimuli in naive rat pups and in pups in which Complete Freund's adjuvant (CFA) was injected in a fore- or hindpaw to produce inflammation (Anseloni, V. C. *et al.*, 2002). Pain thresholds were tested using conductive thermal and mechanical (von Frey filaments) stimuli from P0 (the day of birth) to P21. In noninflamed animals, for noxious thermal stimuli, sucrose-induced analgesia for the hindpaw emerged at P3, peaked at P7–P10, then progressively declined and was absent at P17 (Figure 1). For mechanical forepaw stimuli, sucrose-induced analgesia emerged, and was maximal at ~P10, then declined and was absent at P17. By contrast, maximal sucrose-induced analgesia for mechanical hindpaw stimuli was delayed (P13) compared to that for the forepaw, although it was also absent at P17. In inflamed animals, sucrose reduced hyperalgesia and allodynia assessed with mechanical stimuli (Figure 2). Sucrose-induced analgesia in inflamed animals was initially present at P3 for the forepaw and P13 for the hindpaw, and was absent by P17 for both limbs. Intraoral sucrose produced significantly greater effects on responses in fore- and

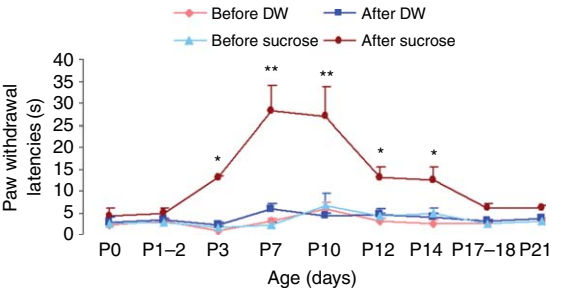

Figure 1 Effects of intraoral sucrose infusion of forepaw withdrawal latencies to thermal stimuli from P0 to P21. Infusion of distilled water (DW) did not influence paw withdrawal latencies ($P > 0.05$) and baseline withdrawal latencies were similar across P0–P21. Sucrose infusion did not significantly influence paw withdrawal latencies at P0–P2 or P17–P21. However, sucrose infusion significantly elevated withdrawal latencies from P3 to P14. Each time point includes a minimum of eight animals. Data are expressed as mean ± standard error of the mean paw withdrawal latency. $^{*}P < 0.01$; $^{**}P < 0.001$.

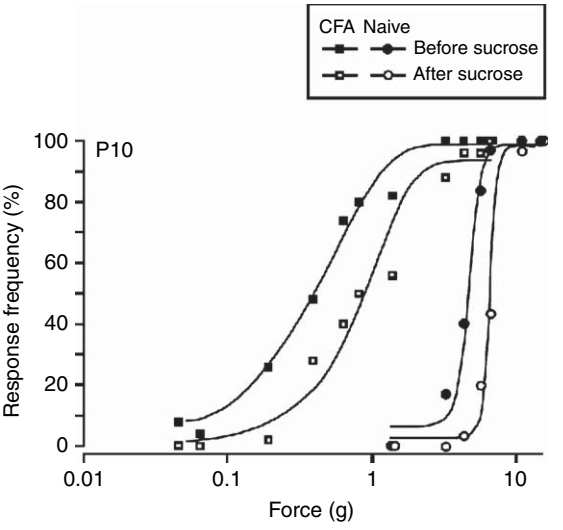

Figure 2 Stimulus–response function curves illustrating the effects of intraoral sucrose on response frequency of the forepaw to mechanical stimuli in noninflamed (naive) and inflamed (CFA) rats at P10; see text for details. Note the leftward shift in the stimulus–response function in inflamed rats compared to naive rats. After inflammation, rats respond to stimuli that are subthreshold in naive rats, indicating the development of inflammation-induced allodynia. There is also an increased response to suprathreshold stimuli, indicating the development of inflammation-induced hyperalgesia. Note that sucrose infusion (open symbols) diminished the response frequency, resulting in a significant rightward shift of the curves for both naive and inflamed rats ($P < 0.001$). Reprinted from Anseloni, V. C., Weng, H. R., Terayama, R., Letizia, D., Davis, B. J., Ren, K., Dubner, R., and Ennis, M. 2002. Age-dependency elicited by intraoral sucrose in acute and persistent pain models. Pain 97, 93–103, with permission from IASP.

hindpaws in inflamed rats than in naive rats indicating that it reduces hyperalgesia and allodynia beyond its effects on responses in naive animals.

The preceding study demonstrated that sucrose-induced analgesia is age-dependent and maximal at P10–P13, and is limited to the preweaning period (<P17) in rats. After P10–P13, the analgesic effect of intraoral sucrose progressively subsides as weaning approaches, and is absent at the approximate time of weaning (P17–P21). Extrapolating to humans, P7 in rats correlates to full-term human newborns and the range of P0–P20 in rats corresponds approximately to 24 weeks of gestation and the toddler stage, respectively, in human infants (Helmuth, L., 2000). Sucrose-induced analgesia in rats thus disappears at a neonatal age when locomotor activity is sufficiently developed for the animal to generate organized escape from noxious stimuli. The age-dependency of sucrose-induced analgesia and its differential maturation for the fore- and hindpaw may be due to developmental changes in endogenous analgesic mechanisms and developmental modulation of the interaction between gustatory and pain modulatory pathways (for review see Anseloni, V. C. *et al.*, 2002). The findings above support the hypothesis that sucrose has a selective influence on analgesic mechanisms and that an enhanced sucrose effect takes place in hyperalgesic, inflamed animals as compared to naive animals. These results indicate that intraoral sucrose alleviates transient pain in response to thermal and mechanical stimuli, and also effectively reduces inflammatory hyperalgesia and allodynia.

The absence of an analgesic effect of sucrose infusion at P0–P2 was surprising given previous reports that intraoral milk infusion was analgesic in P0 pups delivered by cesarean section (Blass, E. M. *et al.*, 1991). The reason for the difference between the two studies is unclear. Stress or changes in opioid mechanisms as a result of natural delivery may compromise the ability of milk and/or sucrose to produce analgesia for the first few postnatal days. Milk also contains a number of individual analgesic sugars and fats, and the combination of these, but not sucrose alone, may be sufficient to produce analgesia immediately after birth. Further studies are needed to address these questions.

4.08.3.2 Neural Circuitry

As reviewed above, the characteristics of sucrose-induced analgesia have been well established in rat pups and human infants. By contrast, nothing is known about the neurobiological substrate underlying this phenomenon. The ability of a small intraoral bolus of sucrose to trigger opiate-mediated analgesia suggests that there are connections from sweet taste-responsive brain neurons to the descending antinociceptive systems. In this regard, it is noteworthy that several gustatory areas have been reported to be involved in analgesia, including the parabrachial nucleus (Bester, H. *et al.*, 1995), insular cortex (Burkey, A. R. *et al.*, 1996), central nucleus of the amygdala (Kalivas, P. W. *et al.*, 1982; Oliveras, J. L. and Besson, J. M., 1988), and lateral hypothalamus. Additionally, tract tracing studies have demonstrated that several gustatory areas project to two major brainstem antinociceptive sites involved in opiate-receptor-dependent analgesia: the midbrain periaqueductal gray (PAG) and the rostroventromedial medullary region that includes nucleus raphe magnus (RMG). For example, the parabrachial nucleus, insular cortex, central nucleus of the amygdala, and lateral hypothalamus densely innervate the PAG and some of these areas directly project to the RMG area (Behbehani, M. M. *et al.*, 1988; Krukoff, T. L. *et al.*, 1993; Behbehani, M. M., 1995; Hermann, D. M. *et al.*, 1997). Thus, there is considerable overlap among, as well as numerous potential anatomical linkages between, components of gustatory pathway and sites known to be involved in centrally mediated analgesia.

To begin to assess these circuits, we used mid-collicular transections as well as immunohistochemistry for the protein product of the immediate early gene c-*fos*, to identify sites involved in the analgesic effect of sucrose in neonatal rats. Previous studies have shown that certain functions of the taste system do not require processing or feedback from higher-order gustatory structures. Adult animals exhibit appropriate motor and discriminative responses to taste stimuli following mid-collicular transections that isolate the parabrachial nucleus (PBN) from the taste thalamus and other forebrain gustatory structures. For example, rats will ingest palatable sweet taste solutions or milk and reject unpalatable bitter taste solutions following mid-collicular transections (Kornblith, C. L. and Hall, W. G., 1979; Grill, H. J. and Norgren, R., 1978; Grill, H. J. and Berridge, K., 1985). Thus, the discriminatory and basic motor aspects of taste behavior are retained in the brainstem caudal to the level of the PBN. Given these findings, we asked whether the neural circuitry necessary for mediating sucrose-induced analgesia in neonatal rats also resides within the brainstem and spinal cord. To assess this, mid-collicular transections that isolated

the PBN, as well as more caudal structures, from mid- and forebrain components of the gustatory pathway were performed (Anseloni, V. C. *et al.*, 2005). Also present posterior to the transection were several structures involved in antinociception, including the caudal PAG and RMG. We found that in the transected pups, the analgesic actions of intraoral sucrose infusion persisted. Moreover, sucrose-induced analgesia was enhanced compared to its actions in the sham pups. This suggested that descending projections from the mid- or forebrain may tonically facilitate central responses to noxious somatosensory input. Consistent with this, transection alone produced a decrease in withdrawal responses to noxious mechanical stimuli, resulting in behavioral hypoalgesia. However, a simple shift in baseline responses did not appear to account for the persistence of sucrose's analgesic effect in the transected pups. Transection alone increased the baseline withdrawal responses to roughly the same degree (30–40%) as did sucrose in the sham animals (40–50%). By contrast, sucrose produced a significantly greater increase (173%) following mid-collicular transection (Figure 3).

The preceding findings indicate that the neural circuitry underlying sucrose-induced analgesia resides within the brainstem and spinal cord. We next assessed c-fos activity elicited by brief intraoral infusion (90 µl in 90 s) of sucrose (0.2 M) or ammonium chloride (a salt stimulus, 0.1 M) to identify candidate brainstem neurons involved in this circuitry (Anseloni, V. C. *et al.*, 2005). Compared to control groups (intact, cannula, distilled water), both sucrose and ammonium chloride induced Fos expression in the rNTS, the first relay in the ascending gustatory pathway. Sucrose also elicited Fos expression in several brainstem areas associated with centrally mediated analgesia, including the PAG and the RMG. Taken together, these findings demonstrate that analgesia elicited by intraoral sucrose does not require involvement of the forebrain. Intraoral sucrose activates neurons in the PAG and RMG, two key brainstem sites critically involved in descending pain modulation.

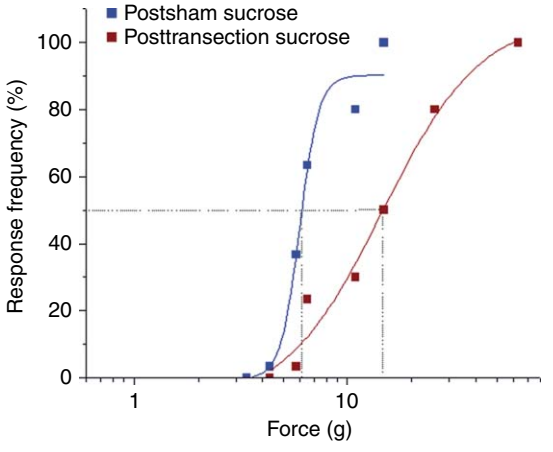

Figure 3 Stimulus–response function curves comparing the effects of intraoral sucrose on response frequency of the hindpaw to mechanical stimuli following sham and mid-collicular transection surgeries in P10–P12 rats. Sucrose after transection had an enhanced analgesic effect compared to sucrose in sham animals, as illustrated by the significant rightward shift in the stimulus–response curve ($P < 0.001$); see text for details.

Previous studies have shown that activation of the PAG and RMG produce analgesia and are two key brain substrates involved in the analgesic actions of opioids. RMG neurons are the main source of descending projections (via the dorsolateral funiculus) to the dorsal horn of the spinal cord. RMG stimulation, or morphine administration, inhibits dorsal horn neurons involved in pain transmission (Fields, H. L. *et al.*, 1991; Behbehani, M. M., 1995). If, as suggested above by the study of Anseloni V. C. *et al.* (2005), intraoral sucrose produces analgesia via activation of RMG neurons, then intraoral sucrose should, similar to direct stimulation of RMG, inhibit spinal cord neuronal responses to nociceptive stimuli. Ren K. *et al.* (1997) found that intraoral sucrose markedly diminished Fos expression in the spinal cord elicited by inflammation of the forepaw. Thus, the effects of intraoral sucrose are similar to those of morphine, in that both blunt dorsal horn neuronal responses to noxious somatosensory input.

4.08.4 Future Directions

Despite our increased understanding of the neurobiological underpinnings and properties of taste analgesia in humans and rodents, significant questions remain. What mechanisms are responsible for the ontogeny and developmentally transient nature of this phenomenon? Where are the specific links where gustatory information accesses central analgesic circuits? What opioid neurotransmitters (e.g., enkephalin, dynorphin) and opiate receptor subtypes are involved, and where are they located? These will be difficult questions to answer, as opioids and opiate receptors are located in numerous components in both the ascending gustatory pathway and

descending antinociceptive circuits. Might analgesia elicited by nursing provide a natural neuroprotective function for the developing nervous system? The ability of natural stimuli to produce analgesia may have important consequences beyond transient or brief pain relief in developing infants. Preterm and certain high-risk infants undergo repeated clinical procedures which produce cutaneous inflammation accompanied by hyperalgesia lasting for several hours or even days (Anand, K. J., 1999). Recent studies have shown that tissue injury during the first few postnatal weeks produces changes in the long-term development of nociceptive circuits and pain thresholds that persist in adult animals (Ruda, M. A. *et al*., 2000; Lidow, M. S. *et al*., 2001; Ren, K. *et al*., 2004). Thus, analgesia produced by natural stimuli during the preweaning period may protect against the deleterious effects of tissue injury and inflammation on the development and/or maturation of nociceptive circuits.

4.09.1 Introduction

Bitter taste has been considered to be part of a warning system designed by nature to prevent organisms from ingesting poisonous substances. Bitter transduction, therefore, appears to be associated with neural networks involved in avoidance behavior. In marked contrast, sweet and amino acid taste (also referred to as umami taste) are thought to act as calorie detectors and consequently elicit attractive behavioral patterns

that promote intake. It turned out recently that in the periphery taste receptor cells form separate populations, one for each taste modality (Chandrashekar, J., 2006). It is apparently not important how a taste receptor cell population is stimulated to elicit the sensation of umami, sweet or bitter, it is only important that it is exited (Zhang, Y. *et al.*, 2003; Mueller, K. L. *et al.*, 2005). In this scenario, the taste receptors fulfill the task to convert a chemical structure into a biochemical response that is propagated to the cerebral cortex, where the activities of neurons reflect the cognitive perception. This chapter focuses on the receptors for sweet, umami, and bitter tastes. During the last ~7 years enormous progress has been in elucidating many of the receptor properties. But still the field is in dynamic expansion. The accumulated knowledge will be summarized with reference to the current problems and to identify future directions.

4.09.2 Bitter-Taste Receptors

4.09.2.1 Discovery of TAS2Rs

A number of reasonable assumptions provided the basis of cloning the bitter-taste receptor genes. First, the observation that the G-protein subunit α-gustducin plays a major role in bitter taste (McLaughlin, S. K. *et al.*, 1992; Wong, G. T. *et al.*, 1996a; 1996b; Ming, D. *et al.*, 1998; 1999; Ruiz-Avila, L. *et al.*, 2000) suggested that bitter receptors are G-protein-coupled receptors (GPCRs). Second, it has been hypothesized that a family of receptors must exist that allows detection of the numerous bitter compounds (Belitz, H. D. and Wieser, H., 1985). Third, it has been anticipated that the receptor genes are linked to chromosomal loci that have previously been demonstrated to influence the sensitivities for various bitter-tasting substances (Lush, I. E., 1981; 1984; 1986; Lush, I. E. and Holland, G., 1988). Searching the human genome data base ultimately led to the identification of the first members of a gene family encoding a new class of GPCRs termed T2Rs (Adler, E. *et al.*, 2000) or TRBs (Matsunami, H. *et al.*, 2000). With the gene sequences at hand several other groups subsequently isolated additional members of this gene family from humans, mice, rats, and various primate species (Bufe, B. *et al.*, 2002; Conte, C. *et al.*, 2002; 2003; Shi, P. *et al.*, 2003; Parry, C. M. *et al.*, 2004; Fischer, A. *et al.*, 2005; Go, Y. *et al.*, 2005). Today the complete repertoire of bitter receptor genes has been identified in humans, mice, rats, dogs, cows, opossums, chickens, frogs, and several fish (Conte, C. *et al.*, 2002; 2003; Go, Y., 2006; Shi, P. and Zhang, J., 2006). Twenty-three of the 25 human *TAS2R* genes are present in two extended clusters on chromosomes 7q34-35 and 12p13.31-13.2, while one each is located on chromosome 5p15.31 and 7q31.32 (Adler, E. *et al.*, 2000; Matsunami, H. *et al.*, 2000; Bufe, B. *et al.*, 2004). In mice, all but two genes are found in two clusters on chromosome 6, the two exceptions being located on chromosomes 2 and 15. Due to the simultaneous cloning in different laboratories the nomenclature of bitter receptor genes is confusing. In this review article the authors use the nomenclature of Bufe B. *et al.* (2002), that has been approved by the human genome project nomenclature committee.

Like many other GPCRs, the coding regions of TAS2Rs are not interrupted by introns (Adler, E. *et al.*, 2000; Matsunami, H. *et al.*, 2000; Bufe, B. *et al.*, 2002; Conte, C. *et al.*, 2002; 2003) and likely fold into seven transmembrane regions with the corresponding intracellular and extracellular domains (Floriano, W. B. *et al.*, 2006; Miguet, L. *et al.*, 2006). TAS2Rs lack, however, any sequence relationship to other members of the GPCR superfamily, but do show sequence relationship among themselves. They also lack the typical signatures of other GPCRs, such as the DRY motif close to transmembrane domain (TMD) 3 and the two conserved cysteine residues in extracellular loops 2 and 3 thought to form disulphide bridges in other GPCRs. TAS2Rs also miss N-linked glycosylation consensus sequences in the N-terminal domain. TAS2Rs are characterized by short N- and C-terminal domains and a well conserved N-linked glyco-sylation consensus sequence in extracellular loop 2. They are therefore considered to form a separate class of GPCRs. Even within a species sequence identities amongst TAS2Rs vary greatly ranging from less then 20% for some members to more than 80% for others. The extracellular parts of the TAS2Rs and the parts of the transmembrane segments facing the extracellular space are less conserved than the intracellular domains and the parts of the transmembrane segments close to the cytoplasm. This is consistent with the idea that the former regions form heterogeneous binding pockets for the numerous bitter compounds, whereas the latter regions engage in G-protein activation that is likely less variable (Meyerhof, W., 2005). The C-terminal domain, which also shows little sequence conservation, could reflect differences in receptor trafficking and/or regulation.

4.09.2.2 Molecular Evolution of *TAS2R* Genes

The available TAS2R repertoires reveal different numbers of genes in humans, mice, rats, dogs, cows, opossums, chickens, frogs, and fish. Whereas chickens have only three genes, their number in mammals and amphibian is in the range of 20–50 (Go, Y., 2006; Shi, P. and Zhang, J., 2006). The high numbers of TAS2Rs in frogs are surprising as most bitter substances are of plant origin and frogs mostly feed on animals. It has been proposed that the TAS2R gene repertoires evolved from multiple ancestors in the lineage leading to teleosts and tetrapods by frequent gene duplications and deactivations with expansions in mammals and amphibia and contraction in chickens. Another characteristic of the TAS2R repertoires across species is a one-to-one orthology for some genes whereas others are lineage or species specific. The lineage specific TAS2Rs appear to be duplicated lately in evolution as their sequences are comparably well conserved and the genes are closely spaced on the chromosomes. These genes may be under positive selection driven by adaptation of species to changing nutritional habits during phylogenetic evolution and detect species specific bitter substances (Bufe, B. *et al.*, 2002; Shi, P. *et al.*, 2003). The *TAS2R* genes with a one-to-one orthology appear to be under more selective constraints and have been proposed to detect bitter compounds encountered by various species (Shi, P. *et al.*, 2003).

Evidence for reduced selective pressure of primate *TAS2R* genes compared with their rodent counterparts comes from the increasing number of pseudogenes from rodents to apes and human and from similar proportions of synonymous to nonsynonymous substitutions (Fischer, A. *et al.*, 2005; Go, Y. *et al.*, 2005). In the hominid lineage, the reduced functional constraints may have been arisen by diminished necessity to detect bitter substances due to decreased consumption of plant food, increased consumption of animal meat and detoxification of food through the controlled use of fire (Wang, X. *et al.*, 2004). Positive selection has also been shown to shape *TAS2R* genes. A sensitive allele of the human glucopyranoside receptor, TAS2R16, was generated during the Paleolithic and, with the migration of *Homo* out of Africa, spread all over the world while the original low sensitivity allele is only found in Africa (Soranzo, N. *et al.*, 2005). It has been proposed that increased sensitivity for frequent toxic glycosides allowed ancient humans to establish healthier diets with low contents of such plant secondary metabolites exerting a selective advantage in carriers of the sensitive allele. The low-sensitivity allele, restricted to Africa with a distribution similar to those of known anti-Malaria alleles, may have been associated with a higher intake of cyanogenic glycosides. A possible consequence could be chronic cyanide poisoning and sickle cell anemia. This provides a selective advantage to carriers of the low sensitivity allele as sickle cell anemia protects against malaria infection (Soranzo, N. *et al.*, 2005). In addition to loss of functional constraints and positive selection, balancing natural selection has been shown as an evolutionary force. It maintains functional nontaster alleles of the phenylthiocarbamide receptor, TAS2R38 (Kim, U. K. *et al.*, 2003; Bufe, B. *et al.*, 2005), in the human but not in the chimpanzee population (Wooding, S. *et al.*, 2004, Wooding, S. *et al.*, 2006).

4.09.2.3 Expression of *TAS2R* Genes in Oral and Extraoral Tissues

4.09.2.3.1 Expression of TAS2R genes in oral tissues

Fully consistent with their role as taste receptor genes, TAS2R messenger ribonucleic acids (mRNAs) have been found by reverse-transcriptase polymerase chain reaction (RT-PCR) and *in situ* hybridization in taste bud cells of all three types of lingual papillae in rodents and humans (Adler, E. *et al.*, 2000; Matsunami, H. *et al.*, 2000; Ueda, T. *et al.*, 2001; Bufe, B. *et al.*, 2002; Kim, M. R. *et al.*, 2003; Behrens, M. *et al.*, 2004; Kuhn, C. *et al.*, 2004; Bufe, B. *et al.*, 2005). TAS2R expression did not overlap with that of TAS1Rs supporting the finding that separate taste receptor cell populations exist for the different taste modalities (Zhang, Y. *et al.*, 2003; Mueller, K. L. *et al.*, 2005; Huang, A. L. *et al.*, 2006). From the number of cells labeled by *in situ* hybridization probes it has been estimated that some 15% of rodent taste bud cells express TAS2Rs (Adler, E. *et al.*, 2000). Based on a smaller set of data a similar estimate has been achieved in humans (Meyerhof, W. *et al.*, 2005). The proportion of TAS2R-positive cells in taste buds was similar for all types of taste papillae (Adler, E. *et al.*, 2000). Differences in TAS2R expression, however, were seen across papillae. Whereas almost all foliate and vallate taste buds contain TAS2R-positive cells, only less than 10% of the fungiform papillae do so (Adler, E. *et al.*, 2000). As gustatory information of fungiform papillae is largely transmitted by the chorda tympani nerve, while

responses from foliate and vallate papillae are transmitted by the glossopharyngeal nerve the question arises whether or not the TAS2R expression pattern generates a chemotopic map. Although this question cannot be answered definitely, it is important to note that for some but not all bitter compounds glossopharyngeal responses differed from those of the chorda tympani (Dahl, M. *et al.*, 1997; Danilova, V. and Hellekant, G., 2003; 2004).

From *in situ* hybridization experiments in rodents with single and mixed TAS2R probes Adler E. *et al.* (2000) concluded that a large number of TAS2R genes, possibly the full repertoire, is expressed in the same subset of taste receptor cells that therefore form a uniform population of bitter-taste cells which could explain the uniformity of bitter taste. This conclusion was supported in phospholipase C-β2 knockout mice that lost their responses to bitter stimuli. When phospholipase C-β2 expression was rescued under the control of various *TAS2R* gene promoters, the animals acquired nerve and behavioral responses to many bitter stimuli (Mueller, K. L. *et al.*, 2005). However, this conclusion is challenged by another *in situ* hybridization study in mice that did not reveal the same degree of homogeneity amongst bitter-taste cells (Matsunami, H. *et al.*, 2000) and by physiological recordings in mouse taste tissues that revealed clear heterogeneity across bitter cells by demonstrating that taste cells responded only to one or two out of a collection of five different bitter compounds (Caicedo, A. and Roper, S. D., 2001). A nonuniform population of bitter receptor cells would be a prerequisite for mammals to discriminate among bitter stimuli. However, this ability has also been disputed (Whitney, G. and Harder, D. B., 1994; Dahl, M. *et al.*, 1997; Delwiche, J. F. *et al.*, 2001; Spector, A. C. and Kopka, S. L., 2002). Perhaps mammals categorize compounds into but can discriminate amongst them within taste modalities.

4.09.2.3.2 Expression of TAS2R genes in extraoral tissues

The recent observation that *TAS2R* gene expression and expression of taste-signaling molecules has been detected in extraoral tissues challenged the role of TAS2Rs as taste receptors. As long as the complete TAS2R repertoire has not been demonstrated to be present in taste tissues, some of them may not function as taste sensors but fulfill other specific tasks. Nevertheless, extraorally expressed TAS2Rs likely exert additional functions. Sites of extraoral TAS2R expression were the solitary chemoreceptor cells in the respiratory epithelium. Irrigation of the respiratory epithelium with bitter compounds elicited trigeminal responses and pronounced respiratory effects (Finger, T. E. *et al.*, 2003). These results indicate that, similar to their oral function to prevent intoxication, nasal bitter receptors could protect mammals from the aspiration of noxious substances. Other sites of TAS2R expression were gastrointestinal cells and the testes (Wu, S. V. *et al.*, 2002; Behrens, M. *et al.*, 2006) suggesting that they may be involved in metabolic and reproductive functions.

4.09.2.4 Functional Properties of Bitter Receptors

4.09.2.4.1 Tuning of TAS2Rs to their agonists

Most of the known properties of TAS2Rs have been uncovered in heterologous expression assays using mammalian and insect cell lines (Chandrashekar, J. *et al.*, 2000; Bufe, B. *et al.*, 2002; Sainz, E. *et al.*, 2007). Usually the recombinant receptors are expressed as chimeras containing N-terminally located domains of bovine rhodopsin (Chandrashekar, J. *et al.*, 2000; Sainz, E. *et al.*, 2007) or rat somatostatin type 3 receptor (Bufe, B. *et al.*, 2002) that serve as cell surface-targeting modules. For some receptors such targeting motifs can be omitted if auxiliary proteins of the receptor transport protein or receptor expression enhancing protein families are coexpressed (Saito, H. *et al.*, 2004; Behrens, M. *et al.*, 2006). Receptor activation is monitored by fluorometric detection of bitter compound-induced changes in cytosolic calcium concentrations in cell lines expressing the promiscuously coupling G-protein subunit Gα15 (Chandrashekar, J. *et al.*, 2000; Bufe, B. *et al.*, 2002) or chimeras of α-gustducin and Gα16 (Ueda, T. *et al.*, 2003; Behrens, M. *et al.*, 2004; Kuhn, C. *et al.*, 2004; Bufe, B. *et al.*, 2005). Alternative approaches rely on the incorporation of radiolabeled GTPγS into purified G-protein α-subunits added to membranes containing the recombinant TAS2Rs (Chandrashekar, J. *et al.*, 2000; Sainz, E. *et al.*, 2007).

With these assays, the cognate bitter compounds for a number of TAS2Rs have been identified (Table 1) and a number of important conclusions have been drawn from the experiments. First, the identified compounds taste bitter confirming the role of TAS2Rs as bitter receptors. Second, TAS2Rs are broadly tuned to detect numerous substances. Some of them are activated by compounds with common substructures. Human TAS2R16 for instance detects numerous β-glucopyranosides and hTAS2R38 various thioamides (Bufe, B.

Table 1 Cognate bitter compounds for TAS2Rs

TAS2R	*Cognate compounds*	*Reference*
hTAS2R4	Denatonium benzoate, PTC	Chandrashekar J. (2006)
mTAS2R5	Cycloheximide, lidocaine	Pronin A. N. *et al*. (2004); Chandrashekar J. (2006)
mTAS2R8	Denatonium benzoate	Chandrashekar J. (2006)
hTAS2R7	Atropine, chloroquine, papaverine, quinacrine, strychnine	Sainz E. *et al*. (2007)
hTAS2R10	Strychnine	Bufe B. *et al*. (2002)
hTAS2R14	Aristolochic acid, α-thujone, picrotin, naphtoic acid	Behrens M. *et al*. (2004); Sainz E. *et al*. (2007)
hTAS2R16	Numerous β-glucopyranosides	Bufe B. *et al*. (2002)
hTAS2R38	Numerous thioamides including PROP and PTC	Kim U. K. *et al*. (2003); Bufe B. *et al*. (2005)
hTAS2R43	Saccharin, acesulfame K, aristolochic acid, 6-nitrosaccharin	Kuhn C. *et al*. (2004)
hTAS2R44	Saccharin, acesulfame K, aristolochic acid	Kuhn C. *et al*. (2004); Pronin A. N. *et al*. (2004)
hTAS2R47	Denatonium benzoate, 6-nitrosaccharin	Pronin A. N. *et al*. (2004)

PROP, 6-*n*-propylthiouracil; PTC, phenylthiocarbamide

et al., 2002; 2005). Human TAS2R7 and TAS2R14 are even more promiscuous and responded to chemically extremely diverse compounds (Behrens, M. *et al*., 2004; Sainz, E. *et al*., 2007). It has been proposed that during evolution different functional constraints shaped bitter-taste receptors to fulfill different tasks. More selective TAS2Rs could detect the prominent plant toxins in a familiar environment, whereas the promiscuous TAS2Rs may be important for accessing novel habitats (Behrens, M. *et al*., 2004). Nevertheless, if the broad tuning is a property of all TAS2Rs, it would easily explain how mammals detect the numerous bitter substances in their environment with a small repertoire of bitter receptors. Third, it appears that the sensitivity of TAS2Rs for their agonists recorded *in vitro* corresponds reasonably well to the sensory performance of mice or human subjects (Chandrashekar, J. *et al*., 2000; Bufe, B. *et al*., 2002; Bufe, B. *et al*., 2005) suggesting that the biochemical properties of the receptors determine perceptive performance. This assumption is impressively supported by experiments in transgenic mice. Wild-type mice are indifferent to β-glucopyranosides. However, if the human *TAS2R16* gene is expressed as a transgene in mice bitter receptor cells the animals acquire sensitivity toward these compounds with parameters similar to those seen in human subjects and hTAS2R16 receptor assays (Mueller, K. L. *et al*., 2005). Fourth, although not examined specifically, it appears from Table 1 that some redundancy exists in TAS2R tuning. For instance, hTAS2R44 shares agonists with hTAS2R43 and hTAS2R14; hTAS2R10 with hTAS2R7; and hTAS2R4 with hTAS2R47. The physiological consequences, if there are any, are unknown. We may speculate here that, possibly, bitter taste would have a backup system at its disposal in the case mutations silence TAS2Rs or that compounds activating several receptors would have greater bitterness than compounds with only one receptor or that compounds with multiple receptors could be detected over a wider concentration range than those with only one.

4.09.2.4.2 Activation of TAS2Rs by agonists

The broad tuning of TAS2Rs immediately raises the question of how these receptors accommodate their ligands. In contrast to neurotransmitter or peptide hormone receptors, which have affinities in the nanomolar or picomolar range for their receptors (Olias, G. *et al*., 2004), TAS2Rs respond to micromolar and millimolar concentrations of their agonists (see references in Table 1). We may imagine that TAS2Rs have loosely fitting binding pockets in which the agonists are accommodated in a relatively unspecific fashion. Or, TAS2Rs may exhibit separate or overlapping highly specific binding sites for their agonists. Considerations about the structure-activities of bitter compounds at their TAS2Rs would support the latter conjecture. Human TAS2R16, for instance, specifically detects β-glucopyranosides but is not activated by β-galactopyranosides or α-glucopyranosides. Variations in the size and hydrophobicity of the aglycon influence critically the potencies of glucopyranosides at hTAS2R16. These data argue for specific interactions of molecular groups of the agonists with definite amino acid residues of the receptor. (Bufe, B. *et al*., 2002). Analogous observations

that have been made with hTAS2R38 support this conclusion (Bufe, B. *et al.*, 2005).

Unfortunately, the molecular architecture of TAS2Rs remained largely unknown. Only one report addressed this question experimentally by mutational analysis and provided limited insight into the interaction of the TAS2Rs with their agonists (Pronin, A. N. *et al.*, 2004). Analyses of domain swapping experiments and chimeras made of the closely related receptors, TAS2R43, which responded to 6-nitrosaccharin, and TAS2R44, which is sensitive to *N*-isopropyl-2-methyl-5-nitrobenzenesulfonamide (IMNB), suggested that amino acid residues responsible for selective receptor activation by IMNB are present in extracellular loop 1 but not 2. Both loops and other parts of the receptor, however, contain residues important for activation of hTAS2R43 by 6-nitrosaccharin. Further analysis uncovered the importance of residue G92 in the extracellular loop of hTAS2R44. Exchange of this residue for the corresponding asparagine of hTAS2R43 made the mutant receptor responsive to both ligands, whereas the reciprocal mutation in hTAS2R43 impaired the activation properties of this receptor. This residue was also of importance for denatonium activation of hTAS2R47, the corresponding mutants N92G and N92A being unresponsive. Also a tryptophan residue present at position 88 of these receptors and conserved in 21 out of 25 human TAS2Rs was critical for agonist activation of hTAS2R43, hTAS2R44, and hTAS2R47. Although these findings are of great importance and interest, they do not allow precise conclusions to be drawn about the binding motifs of TAS2Rs. The analyzed residues may be involved in ligand binding, activation mechanisms, or globally alter the structure of the receptors (Meyerhof, W., 2005).

4.09.2.4.3 G-protein coupling

There are ~20 different Gα subunits falling into four major classes Gαs, Gαi, Gα12, and Gαq (Gudermann, T. *et al.*, 1997). α-Gustducin, a Gαi-type protein closely related to visual transducin, has originally been identified as a lingual G protein present in a subset of taste receptor cells and been suggested to transduce taste stimuli (McLaughlin, S. K. *et al.*, 1992). Biochemical, physiological, and genetic studies since then confirmed that α-gustducin is critically involved in bitter transduction (Wong, G. T. *et al.*, 1996a; 1996b; Ming, D. *et al.*, 1998; Ming, D. *et al.*, 1999; Wong, G. T. *et al.*, 1999; Caicedo, A. *et al.*, 2003). Direct proof was finally obtained by showing that agonist activation of recombinant mT2R5 in insect cell membranes resulted in GDP/GTPγS exchange in exogenously added purified α-gustducin in the presence of purified β/γ G-protein subunits (Chandrashekar, J. *et al.*, 2000).

However, these results do not rule out the possibility that TAS2Rs may couple to other G-protein α-subunits. In fact, in human embryonic kidney cells previously transfected with DNA for mTAS2R5 that do not express α-gustducin, cycloheximide stimulation activated extracellular signal-regulated kinase activity in a pertussis toxin sensitive fashion, suggesting that this bitter receptor also couples to Gi/o-type G-proteins (Ozeck, M. *et al.*, 2004). This suggestion has been confirmed by reconstituting signal transduction of recombinant mTAS2R5, hTAS2R7, hTAS2R14, hTAS2R43, and hTAS2R47 in insect cell membranes in the presence of purified G-protein subunits (Sainz, E. *et al.*, 2007). None of the receptors coupled to Gαs or Gαq. These experiments demonstrated that members of the TAS2R family are capable of signaling through multiple Gαi subunits, including transducin, Gαi, and Gαo, but not through Gαs- and Gαq-type G-proteins. The findings are also in line with observations made in α-gustducin gene-targeted mice showing that bitter responses were clearly impaired but not abolished (Caicedo, A. *et al.*, 2003; Wong, G. T. *et al.*, 1996a) and with findings showing that transducin is present in taste tissue, partially rescues gustucin null mice, and functionally couples to bitter-taste receptors (He, H. T. *et al.*, 1990; Ruiz-Avila, L. *et al.*, 1995; Yang, H. *et al.*, 1999).

TAS2Rs activate phospholipase C-β2 but not through Gαq suggesting that they do so via β/γ G-protein subunits (Sainz, E. *et al.*, 2007). Searches for such subunits that are involved in bitter taste identified Gγ13 which colocalizes with α-gustducin in taste receptor cells and physically interacts with Gβ1, a subunit also expressed in taste cells (Huang, L. *et al.*, 1999). Blocking experiments with specific antibodies led to the proposal that the heterotrimeric G-protein may be composed of α-gustducin and Gβ1/γ13 or Gβ3/γ13 (Huang, L. *et al.*, 1999; Rossler, P. *et al.*, 2000). Reconstitution experiments with membranes containing recombinant receptors and purified G-protein subunits demonstrated that mTAS2R5, hTAS2R7, and hTAS2R47 indeed couple to Gβ1/γ13 but also to Gβ3/γ13 (Sainz, E. *et al.*, 2007). Together, the available data suggest that complex rules govern TAS2R-G-protein coupling and that coupling is influenced by the precise concentrations of subunits of all three classes and their individual affinities for each other and for the receptors.

4.09.2.5 Polymorphisms and Functional Heterogeneity of TAS2Rs

Genetically determined differences in bitter-taste sensitivity for various compounds have been seen in mice and mapped to specific chromosomal loci (Lush, I. E., 1981; 1984; 1986; Lush, I. E. and Holland, G., 1988). One of these loci encodes the bitter-taste receptor TAS2R5 of which strain specific functionally distinct variants exist that determine taste sensitivities for cycloheximide in strains of mice (Chandrashekar, J. *et al.*, 2000). Thus, there is a molecular basis for explaining taste sensitivity ranging from genotype to receptor properties and sensory performance. In humans, inherited differences in bitter-taste sensitivity are known for some 70 years when it has been discovered that there are genetically determined pronounced individual differences in tasting phenylthiocarbamide (PTC; Blakeslee, A. F., 1931; 1932; Fox, A. L., 1932). PTC-tasters have been reported to taste PTC and chemically related compounds, such as propylthiouracil, at micromolar concentrations, whereas nontasters are taste-blind to these compounds even when they were exposed to them at several 100-fold higher concentrations (Bufe, B. *et al.*, 2005). Eventually, positional cloning identified the *hTAS2R38* gene as a receptor for PTC and showed that three nonsynonymous single nucleotide polymorphisms, SNPs, define different hTAS2R38 haplotypes (Figure 1), of which two are frequent (Kim, U. K. *et al.*, 2003). Depending on the amino acids present in the positions affected by the SNPs, the so-called PAV haplotype is associated with high sensitivity for PTC, whereas the AVI haplotype is linked to nontaster status (Kim, U. K. *et al.*, 2003). A subsequent study then demonstrated that the different hTAS2R38 haplotypes encode functionally distinct hTAS2R38 variants and their sensitivities monitored *in vitro* determine perceptual performance of human subjects (Bufe, B. *et al.*, 2005). Thus, also in humans we have a clear indication that the TAS2R genotype determines the functional properties of the encoded bitter receptor and, these in turn, are crucial for the sensory abilities of subjects.

A comprehensive evaluation of sequence and haplotype variation in the human *TAS2R* gene repertoire identified substantial coding sequence diversity. In a worldwide population sample of 55 individuals, more than four variant amino acid positions were found on average per *TAS2R* gene. Together, the 25 *hTAS2R* genes encode 151 different protein-coding haplotypes, yet some show translational stop codons (Kim, U. *et al.*, 2005). It is reasonable to assume that many of the variant receptors differ in their functional properties toward ligands by showing no responses, or altered ligand spectra, or modified sensitivities for agonists. This has already been shown for the alleles specifying hTAS2R16-N172 and

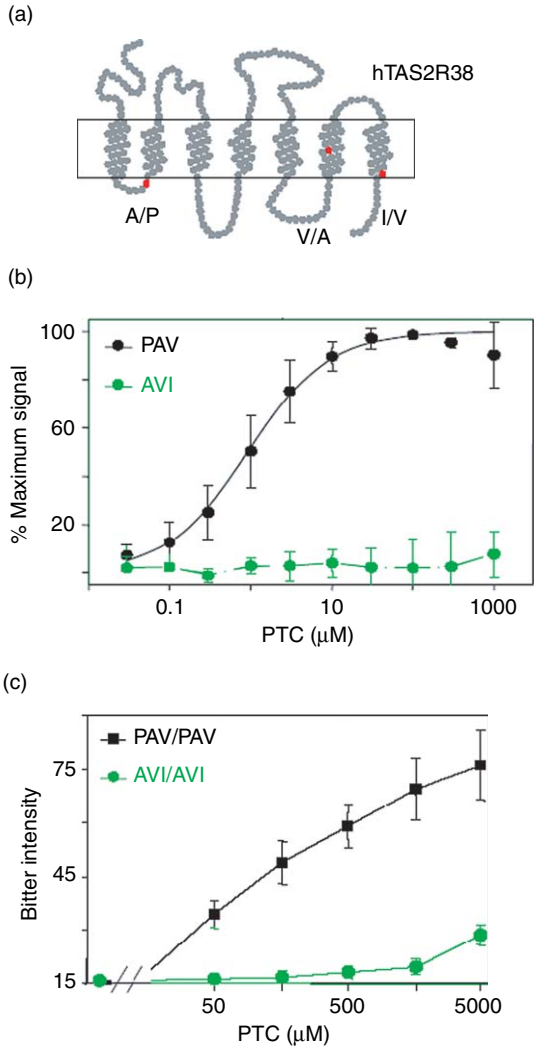

Figure 1 Molecular basis of tasting phenylthiocarbamide. (a) Schematic representation of TAS2R38. Each circle represents an amino acid residue. Amino acid residues in positions 49, 262, and 296 that are affected by single nucleotide polymorphisms are depicted in red and the specific amino acids present in these positions are indicated. (b) Postthreshold bitter intensity ratings of subject groups genotyped to be PAV or AVI homozygous. Please note the pronounced differences in taste sensitivity. (c) functional responses of hTAS2R38-PAV and hTAS2R38-AVI variants recorded in transfected cell lines. The differences in receptor activation closely resemble those seen in the taste experiment shown in (b). Data from Kim, M. R. *et al.* (2003) and Bufe, B. *et al.* (2005).

hTAS2R16-K172 (Soranzo, N. *et al.*, 2005). We may also expect that the functional differences of TAS2Rs translate into perceptual differences in the population. This conclusion is supported by the observed differences in tasting chloramphenicol, strychnine, and quinine across subjects (Blakeslee, A. F., 1935; Sugino, Y. *et al.*, 2002).

4.09.2.6 Implications for Nutrition

It is still a matter of speculation to what extent, if at all, differences in taste sensitivities, particularly bitter sensitivity influences nutritional behavior. Food choice is determined by many parameters with the taste of food being crucial (Drewnowski, A., 1997; 2001). However, a mechanistic explanation is currently unavailable. It has been pointed out that bitter taste contributes to the enjoyment of food and beverages (Drewnowski, A., 2001). In contrast, moderate or strong bitter taste may lead to rejection of healthy compounds (Drewnowski, A. and Gomez-Carneros, C., 2000). Based on the finding that individual TAS2Rs mediate bitter taste for specific compounds and on the conjecture that TAS2R variants determine interindividual bitter-taste sensitivities, we have reason to expect that rejection of bitter substances occurs more easily in subjects carrying high-sensitivity haplotypes than in carriers of low-sensitivity haplotypes. Many studies have been carried out that aimed at associating PTC taster status or hTAS2R38 genotypes with intake behavior and risks for diseases (Drewnowski, A., 2004; Duffy, V. B. *et al.*, 2004b). Indeed such associations have been reported in some studies for preferences for vegetables, fruits, fats, alcohol, and sweeteners (Bartoshuk, L. M., 1979; Drewnowski, A. and Rock, C. L., 1995; Tepper, B. J. and Nurse, R. J., 1997) and risks for goiter, alcoholism, cancer, and depression (Harris, H. *et al.*, 1949; Facchini, F. *et al.*, 1990; Pelchat, M. L. and Danowski, S., 1992; Duffy, V. B. *et al.*, 2004a; Joiner, T. E., Jr. and Perez, M., 2004) while another study did not find such associations (Timpson, N. J. *et al.*, 2005). Also for the hTAS2R16-K172 low-sensitvity allele an association with risk for alcoholism has been detected (Hinrichs, A. L. *et al.*, 2006). Perhaps, all these studies may be biased by the fact that the food items monitored, i.e., vegetables or fruits in general, contain numerous bitter compounds while hTAS2R38 detects only thioamides. Future association studies should look into foods that are rich in hTAS2R38 agonists. To the authors' knowledge, to date only one preliminary study is available, which showed that PTC tasters avoided intake of plant-derived food containing possible hTAS2R38 agonists (Sandell, M. A. and Breslin, P. A., 2006).

4.09.3 Sweet-Taste Receptors

4.09.3.1 Tas1Rs

4.09.3.1.1 Tas1Rs belong to family C G-protein-coupled receptors

The receptors for sweet (Tas1R2 + Tas1R3 function as a sweet receptor) and umami (Tas1R1 + Tas1R3 also function as an umami receptor) taste qualities are GPCRs that, by their protein sequence and homology to other GPCRs, can be assigned to family C. This family has the typical 7TM spanning domain as seen in family A (rhodospinlike GPCRs) but also contains a large extracellular domain that is known to be the orthosteric endogenous ligand-binding domain. Other family members include the metabotropic glutamate binding receptors (mGluRs), calcium-sensing receptors, metabotropic gamma-aminobutyric acid (GABA) receptors and several putative odorant receptors. Although it is now thought that most GPCRs dimerize along their TM domains, family C receptors are known to be obligate dimers that dimerize along their extracellular domains as well as their TM domains. The Tas1 receptors are variously called Tas1R, Tas1R, and Tas1R. At the amino acid level Tas1Rs are 26–34% identical with each other, and ~22–25% identical with mGluRs. The similarity of the Tas1Rs to mGluRs is much higher, ranging from 36% to 43%, making them members of GPCR family C. Family C GPCRs include the mGluRs, calcium-sensing receptors, metabotropic GABA receptors, and a variety of odorant (fish) and pheromone-sensing receptors. A truncated taste-expressed variant of mGluR4 (taste-mGluR4) is present in ~40–70% of taste buds and may also function as an umami receptor (Chaudhari, N. *et al.*, 2000). Below we review what is known about the structure of family C receptors from crystal studies of mGluRs.

4.09.3.1.2 Structure–function studies of family C receptors' venus flytrap module

In addition to the heptihelical TMD common to GPCRs from family A, family C GPCRs have large extracellular region composed of two domains: the venus flytrap module (VFTM, ~500 residues) and the cysteine-rich domain (CRD, ~70 residues; Jingami, H. *et al.*, 2003). The VFTM is a two-lobed clamshell-like structure. The CRD lies between the VFTM and the heptahelical TMD. The CRD has nine highly conserved cysteines within its span of ~70 residues. Based

on extensive structure–function studies of family C receptors, the crystal structure of mGluR1, mGluR2, and mGluR3 (see below), and homology to periplasmic sugar and amino acid transporters, it is highly likely that the VFTM is the receptor's primary ligand-binding domain (Hermans, E. and Challiss, R. A., 2001). It is thought that ligand binding occurs independently to one or both monomers of each dimeric receptor. The ligand-binding site for the endogenous ligand lies in a cleft between the two prominent lobes, with the ligand fitting like a pearl inside a closed oyster. Family C GPCRs are obligate homodimers or heterodimers that dimerize via a discontinuous set of contacts in lobe 1 of the VFTM.

There are a number of structures of the VFTM (mGluR1) and VFTM + CRD (mGluR3) (Kunishima, N. *et al.*, 2000; Tsuchiya, D. *et al.*, 2002; Muto, T. *et al.*, 2007). The crystal structure of the homodimeric mGluR1–3 VFTM consists of two asymmetrical mirror-image monomers. Each VFTM monomer has two lobes that together form a clamshell. The two monomers dimerize by interacting along each lobe 1; the two lobes 2 have no part in the dimerization (Kunishima, N. *et al.*, 2000). Lobe 1 and lobe 2 of each monomer approach each other and their intersection forms the cleft that binds ligand. The ligand-bound, closed conformation of the monomer is the active form. Upon ligand binding and closure of the cleft, the dimer interface rotates upon itself, which brings the two lobes 2 within closer proximity. In mGluR1 the majority of ligand-contacting residues in lobe 1 make direct hydrogen bonds with glutamate, while those in lobe 2 make water-mediated hydrogen bonds and salt bridges (Jingami, H. *et al.*, 2003).

Tas1Rs and other family C GPCRs are expected to dimerize and to bind ligands in a manner similar to mGluR1. Comparing Tas1R and mGluR VFTMs (independently of the receptors' CRDs and TMDs) reveals amino acid identities of ~25% and similarities ~41%. The predicted secondary structures of helices and β-strands of the extracellular domains of Tas1Rs match that of the crystal structure of mGluR1 at nearly every point. The conformational change in family C GPCRs that takes place upon ligand binding appears to be transmitted from the VFTM and CRD to the TMD helical bundle, then onward to the cytoplasmic surface, where it contacts and activates the G protein.

4.09.3.1.3 Cysteine-rich domain structure

Recently a crystal structure of mGluR3 VFTM + CRD was published showing for the first time the structure of the CRD (Muto, T. *et al.*, 2007), which contains three β-sheets composed of two antiparallel β-strands. Eight of the nine conserved cysteines formed four structurally stabilizing disulphide bonds within the structure. A ninth cysteine forms a disulphide bond with a conserved cysteine at the bottom of lobe 2 of the same monomer VFTM. This structure is likely to hold for all the family C receptors except for the GABA receptors, which do not have the conserved cysteines in its linker domain. The CRD, with its connection to the motion of lobe 2 of the VFTM via the disulphide linkage is likely to be critical for transmittal of the conformational change from the ligand-binding VFTM to the TMD. The structure of the CRD suggests that there is a reorientation of the ends of the CRD from 104–126 Å to 46–90 Å apart between the resting and the active state of the VFTM. This suggests an activation mechanism that involves movements of the two TMDs relative to one another upon receptor activation (Muto, T. *et al.*, 2007). However, it is currently unknown how the VFTMs communicate with the TMDs and to what extent intra-TMD versus inter-TMD conformational change contributes to receptor activity.

4.09.3.1.4 Role of the transmembrane domain in family C G-protein-coupled receptors

A hallmark of GPCRs is that they have seven transmembrane helices constituting a TMD. Another key feature of GPCRs is that they mediate their intracellular actions via coupling to and activation of G proteins. Thus, activation of family A receptors by binding of ligand within the TMD is transmitted to the G protein by cytoplasmic loops adjacent to the TMD, whereas, activation of family C receptors by ligand binding within the VFTM is transmitted to the TMD and then by cytoplasmic loops to the G protein. The solved crystal structures of bovine rhodopsin have been widely used as a structural templates to construct homology models of diverse GPCRs using comparative modeling techniques (Visiers, I. *et al.*, 2000; 2002; Malherbe, P. *et al.*, 2003; Miedlich, S. U. *et al.*, 2004; Petrel, C. *et al.*, 2004). The crystal structures of bovine rhodopsin are at present the only solved structures of any GPCRs that include the heptahelical TMD (Palczewski, K. *et al.*, 2000; Teller, D. C. *et al.*, 2001; Okada, T. *et al.*, 2002). The supposition that the general topology of the TMD of rhodopsin is shared by most or all other types of GPCRs, including family C receptors, is supported by the following two points. First, numerous

studies indicate that allosteric binding sites of several family C receptors are within their TMDs. For example, several noncompetitive antagonists and agonists bind within the TMDs of mGluR1, mGluR5, and the calcium-sensing receptor (Pagano, A. *et al.*, 2000; Malherbe, P. *et al.*, 2003; Petrel, C. *et al.*, 2004). Second, although the overall sequence homology of TMDs between GPCRs in families A and C is low, key residues that define the TM helices are conserved in rhodopsin and in family C GPCRs.

4.09.3.2 Discovery of Tas1Rs

4.09.3.2.1 Orphan receptors Tas1R1 and Tas1R2

The taste receptors Tas1R1 and Tas1R2 were first identified in taste cell-specific libraries (Hoon, M. A. *et al.*, 1999). It was originally proposed that mTas1R2 might be a bitter-responsive receptor and that mTas1R1 might be a sweet-responsive taste receptor; the rationale being that Tas1R1 is expressed at the front of the tongue (which is sometimes thought to be more sensitive to sweet) and that Tas1R1 gene maps nearer to the *sac* locus at the distal end of mouse chromosome 4 (Hoon, M. A. *et al.*, 1999). While it is true that both Tas1R1 and Tas1R2 map to the distal end of mouse chromosome 4, refined mapping studies indicated that Tas1R1 and Tas1R2 are several centimorgans away from the *sac* locus, much too far to be the *sac* gene itself (Li, X. *et al.*, 2001).

The taste cell-specific expression of Tas1R1 and Tas1R2 suggested that both receptors might play roles in taste transduction. *In situ* hybridization showed that Tas1R1 and Tas1R2 have different expression patterns in rat taste tissue: rTas1R1 is localized to geschmackstreifen (taste stripe) and fungiform papillae, and rTas1R2 is localized primarily to circumvallate and foliate papillae. The significance of this regional expression pattern is unclear, since it does not correspond to any known pattern of tastant sensitivity in rodents (Lindemann, B., 1999; Sako, N. *et al.*, 2000). Prior to the discovery of Tas1R3, the function of the Tas1R1 and Tas1R2 orphan receptors could not be studied in heterologous cells because as was later shown, Tas1R1 and Tas1R2 form obligate heterodimers with Tas1R3 to function, hindering identification of their natural ligands.

4.09.3.2.2 ID of possible umami receptors: truncated mGluR4, mGluR1

A truncated taste-expressed variant of mGluR4 (taste-mGluR4) was proposed to function as an umami receptor. By *in situ* hybridization, this receptor is present in ~40–70% of the taste buds examined (Chaudhari, N. *et al.*, 2000). Taste mGluR4 displays the characteristics of an umami receptor, with sensitivity to glutamate in the millimolar range, consistent with concentrations known to elicit the sensation of umami. Heterologously expressed taste-mGluR4 shows two other hallmarks of the umami response: it is activated by L-AP4, which elicits a taste similar to L-glutamate in rats, and it is potentiated by 5′-ribonucleotides.

Upon identification of Tas1R3, it became possible to show that the combination of Tas1R1 + Tas1R3 gave rise to a receptor that was sensitive to a variety of L-amino acids including monosodium glutamate suggesting that this combination of Tas1Rs was an umami receptor (Li, X. *et al.*, 2002a; Zhao, G. Q. *et al.*, 2003).

4.09.3.2.3 Identification of Sac locus GPCR Tas1R3 – Tas1R3 is Sac

Inbred strains of mice vary widely in their behavioral and electrophysiological responses to saccharin, sucrose and other compounds that humans perceive as sweet. The *sac* locus was identified as the primary genetic determinant in mice of preference for saccharin and other sweet compounds, distinguishing taster strains (e.g., C57BL/6) from nontasters (e.g., DBA/2; Fuller, J. L., 1974; Lush, I. E., 1989; Lush, I. E. *et al.*, 1995; Blizard, D. A. *et al.*, 1999). To identify candidates for the *sac* gene we searched the sequence of the distal end of mouse chromosome 4 (to which *sac* maps) for genes that might encode GPCRs and other signal transduction elements. This search yielded Tas1R3, a previously unknown GPCR located within 20 kbp of the genetic marker closest to *sac* (Max, M. *et al.*, 2001). Tas1R3 is the third member of the Tas1R taste receptor family, and is most closely related to Tas1R1 and Tas1R2. *In situ* hybridization and immunohistochemistry showed that Tas1R3 is expressed selectively in a subset of taste receptor cells. Sequence analysis of mTas1R3 from eight independently derived strains of mice identified specific polymorphisms (T55A and I60T) that assort between taster and nontaster strains (Max, M. *et al.*, 2001). Other laboratories also identified Tas1R3 by RT-PCR or genomics-based approaches (Bachmanov, A. A. *et al.*, 2001; Kitagawa, M. *et al.*, 2001; Montmayeur, J. P. *et al.*, 2001; Nelson, G. *et al.*, 2001; Sainz, E. *et al.*, 2001). Transgenic expression of the taster form of Tas1R3 converted nontaster mice into tasters, demonstrating that Tas1R3 is

indeed *sac* (Nelson, G. *et al.*, 2001; Damak, S., personal communication).

4.09.3.2.4 Are there other Tas1Rs?

A fourth related gene known as GPRC6A is related to Tas1R1-3 by 20–24% identity. It has been speculated that this gene might be a taste receptor gene by several groups; however, convincing expression in taste cells has not been found to date. Other studies identify this receptor as either an amino acid receptor or a second calcium-sensing receptor with important function in bone (Pi, M. *et al.*, 2005; Christiansen, B. *et al.*, 2006). The latter work is particularly compelling because there is extensive expression of this receptor in bone and it shows responses to calcium, calcium mimetics, and to an important bone peptide, osteocalcin. It remains to be seen if there is a role for this receptor in taste although as this juncture it appears unlikely.

4.09.3.3 Functional Identification of Tas1Rs

4.09.3.3.1 Tas1R2 + Tas1R3 is the primary sweet receptor

Damak S. *et al.* (2003) found that knockout mice lacking Tas1R3 showed no behavioral or nerve response to noncaloric sweeteners, and diminished responses to sugars and umami compounds. Zhao G. Q. *et al.* (2003) observed that knockout mice lacking both Tas1R2 and Tas1R3 had no responses to sweet compounds; mice lacking both Tas1R1 and Tas1R3 had no responses to umami compounds. Zhao G. Q. *et al.* (2003) also showed that mice expressing human Tas1R2 as a transgene were responsive to human-specific sweeteners such as aspartame and thaumatin that are detected by humans but not mice.

Calcium-imaging assays of HEK 293 cells transfected with Tas1R2, Tas1R3, and a reporter G-protein showed responses to a wide range of sweet ligands (Nelson, G. *et al.*, 2001; Li, X. *et al.*, 2002a; Jiang, P. *et al.*, 2004). If either Tas1R2 or Tas1R3 was omitted from the transfection no responses to sweet compounds were detected, leading to the conclusion that the combination of Tas1R2 + Tas1R3 is a broadly responding sweet receptor. In contrast, cells transfected with Tas1R1, Tas1R3, and the reporter G protein responded to amino acids, but not to sweeteners, indicating that the combination of Tas1R1 + Tas1R3 is an umami receptor (Nelson, G. *et al.*, 2001; Li, X. *et al.*, 2002b; Nelson, G. *et al.*, 2002). Apparently, Tas1R3 provides a common element necessary for the proper function of both sweet and umami receptors. Initially, it was thought that ligand-binding determinants would be present only in Tas1R1 and Tas1R2, but not in Tas1R3; however, it appears that Tas1R3 also contributes to the ligand-binding process (see below). Although, heterologous expression of Tas1R1 or Tas1R2 alone yielded no responses to either sweet or umami compounds, expression of Tas1R3 alone yielded responses to trehalose, but not to other sweeteners (Ariyasu, T. *et al.*, 2003; Jiang, P., personal communication) although high concentrations of natural sweeteners appear to be sensed by homodimers of Tas1R3. Like other family C GPCRs, the Tas1Rs probably function as dimers (heterodimers, and in some cases homodimers).

HEK cells expressing hTas1R2 + hTas1R3 respond to all sweet-taste stimuli tested: sugars (sucrose, fructose, galactose, glucose, etc.); amino acids (glycine and D-tryptophan); sweet proteins (brazzein, monellin, and thaumatin); and synthetic sweeteners (cyclamate, saccharin, ace K, aspartame, dulcin, neotame, and sucralose; Nelson, G. *et al.*, 2001; Jiang, P. *et al.*, 2004; Xu, H. *et al.*, 2004). All of these responses are inhibited by the sweet-taste inhibitor lactisole, which acts on the TMD of Tas1R3 (Xu, H. *et al.*, 2004; Jiang, P. *et al.*, 2005a; Winnig, M. *et al.*, 2005). These results, along with the observation that human perception of sweet taste is inhibited by lactisole (Sclafani, A. and Perez, C., 1997). Schiffman S. S. *et al.* (1999) argue that Tas1R2 + Tas1R3 is the primary or the only sweet-taste receptor although that knockout Tas1R3 mice still respond to natural sweeteners suggests that there may be some alternative sugar-sensing mechanism that remains in the absence of the sweet receptor.

4.09.3.4 Ligand-Binding Sites on Tas1Rs

The sweet receptor appears to have multiple sites of interaction for sugars and sweet-tasting artificial compounds. The orthosteric site for sugars is likely to be the closed cleft of the VFTM Tas1R2, and perhaps the cleft of the VFTM of Tas1R3. Artificial sweeteners may also interact with the closed cleft of the VFTM of Tas1R2 in sites overlapping that of the orthosteric site for natural sugars as well as an allosteric site within the TMD of Tas1R3. We have proposed that the larger, noncarbohydrate-containing, naturally occurring peptide sweeteners found in some plants may interact with both the CRD of Tas1R3 and the VFTM of Tas1R2 (Jiang, P. *et al.*, 2004; Maillet, E., personal communication) although other groups have suggested that these proteins interact with the open

cleft of both VFTMs (Morini, G. *et al.*, 2005; Walters, D. E. and Hellekant, G., 2006).

4.09.3.4.1 Orthosteric binding site within the VFTM of Tas1R2

Work from our laboratory indicates that the VFTM of Tas1R2 is one orthosteric binding site for natural sugars as well as forming a binding site for dipeptide and several other artificial sweeteners. We concluded this from studies where we mutated numerous amino acids that line the VFTM cleft and tested the resulting receptors for specific defects in the receptors ability to be activated by a variety of sweeteners (Maillet, E., personal communication). We have also employed receptors composed partly of human and partly of mouse sequences (chimeric receptors) to show which domains of the receptor are required for specific responses to sweeteners that only humans and other primates can taste (dipeptide sweeteners, cyclamate, brazzein, monellin, and others).

4.09.3.4.2 Activity assays map the sweet receptor aspartame interaction site to the VFTM of hTas1R2

Scientists in our laboratory assayed the effects of sweeteners on heterologously expressed mismatched receptors from mouse and human. While mTas1R2 + mTas1R3 responded to D-tryp, saccharin, and sucrose, but not to the human-specific sweeteners (i.e., aspartame, monellin, and brazzein), the interspecies pairing hTas1R2 + mTas1R3 responded to aspartame and most other sweeteners, but not brazzein. These results indicate that responsiveness to aspartame requires the human form of Tas1R2, but does not require the human form of Tas1R3.

A chimeric receptor with the VFTM of human Tas1R2 and the rest from mouse Tas1R2 paired with mTas1R3 (i.e., hVFTM-CRD/mTMDT1R2 + mT1R3) gave responses to aspartame (Figure 2(a)). This indicates that responsiveness to aspartame requires human residues within the VFTM–CRD of Tas1R2, and not human residues within the TMD of Tas1R2. To localize the residues of hTas1R2 required for responsiveness to aspartame better we made additional mouse/human and human/mouse chimeras within the VFTM–CRD of TAS1R2 (Figure 2(b)) and coexpressed them with mTas1R3. The pairing of human/mouse chimeras h1-468/mT1R2 or h1-577/mT1R2 with mT1R3 gave normal responses to aspartame and neotame (Figure 2(b)). This indicated that responsiveness to aspartame and neotame requires human residues within residues 1–468 of the VFTM of hTas1R2 – the rest of Tas1R2 and all of Tas1R3 can be from mouse and still support responses to these human-specific dipeptide sweeteners. The pairing of mouse/

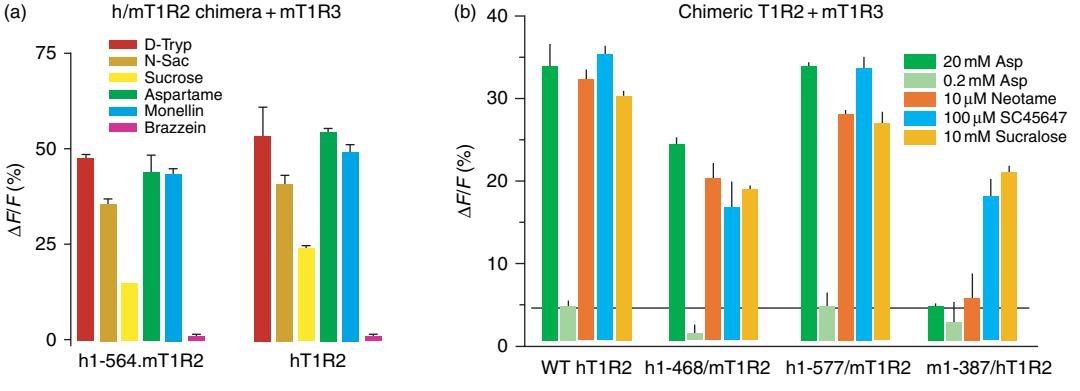

Figure 2 Sweet-receptor responsiveness to aspartame (Asp) and neotame requires human-specific residues within the venus flytrap module (VFTM) of TAS1R2. (a) HEK293E cells transiently transfected with the human/mouse chimera h.1–564.mTas1R2, mTas1R3, and Gα16-i3 were assayed for calcium mobilization in response to the indicated sweet ligands (see methods for details). h1–564.mTas1R2 Contains the extracellular domain of hTas1R2 and the transmembrane region of mTas1R2. Its response profile is comparable to that of hTas1R2. (b) Human/mouse and mouse/human chimeras of Tas1R2 were constructed and coexpressed in HEK cells along with mTas1R3 and Gα16-i3. SC45647 and sucralose served as positive controls for activity. By our naming convention h1-468/mTas1R2 contains residues 1–468 from hTas1R2 and the remainder from mTas1R2. Tas1R2 chimeras with residues 1–468 (VFTM) or 1–577 (VFTM plus part of cysteine-rich domain) from hTas1R2 were responsive to both aspartame and neotame. A Tas1R2 chimera containing mouse residues 1–387 (amino terminal two-thirds of VFTM) from mTas1R2 and the remainder from human Tas1R2 did not respond to aspartame or neotame. We conclude that specific human residues within the VFTM of hasS1R2 are required for responsiveness to aspartame and neotame. ΔF/F, the change of fluorescence at peak over the baseline fluorescence.

human chimera m1-387/hT1R2 with mTas1R3 gave no responses to aspartame or neotame (Figure 2(b)), indicating that one or more residues in the amino terminal two-thirds of the VFTM of hTAS1R2 are necessary for responsiveness toward aspartame and neotame. Based on mapping the interaction of aspartame and neotame to the VFTM of Tas1R2 and the overall homology of the Tas1Rs to mGlurR1, we reasoned that aspartame might bind within the cleft of the VFTM in a manner similar to that of glutamate in mGluR1.

To test this idea, scientists in our laboratory used homology modeling, automatic docking, chimeric and mutant receptors, and activity assays with heterologously expressed receptors to identify the potential binding site(s) within the VFTM of hTas1R2 for aspartame and neotame (Figure 3). We constructed models of Tas1R2 + Tas1R3 based upon the crystal structures of mGluR1 and used them to dock various sweeteners. For aspartame and neotame, our docking studies predicted that the NH^{3+} of aspartame and NH^{2+} of neotame interact through salt bridges with the negatively charged carbonyl groups of Tas1R2 Asp278 and Asp307, and through hydrogen bonds with a backbone oxygen atom of Ser303. The negatively charged carbonyl groups (COO–) of aspartame and neotame are proposed to interact through hydrogen bonds with the NH backbone atoms of Tas1R2 Arg383 and Val384. The phenyl groups of aspartame and neotame are proposed to interact through pi-pi interactions with Tas1R2 Tyr215, and through hydrophobic interactions with Pro277. Morini G. *et al.* (2005) have also modeled the structure of the sweet receptor VFTMs (based on the structure of the VFTM of the mGluR1), and proposed that aspartame could bind within the VFTMs of both TAS1R2 and TAS1R3. The predictions of our model and theirs are in general agreement with regard to the interaction of aspartame with the VFTM of TAS1R2 (both models identified S165, E302, and Y215 as potential interactions), although, our model makes more extensive predictions of potential contacts for aspartame in the VFTM of TAS1R2. Furthermore, based on our activity assays with hTAS1R3 homodimers (unpublished data) we think it unlikely, although theoretically possible, that aspartame binds to the VFTM of TAS1R3.

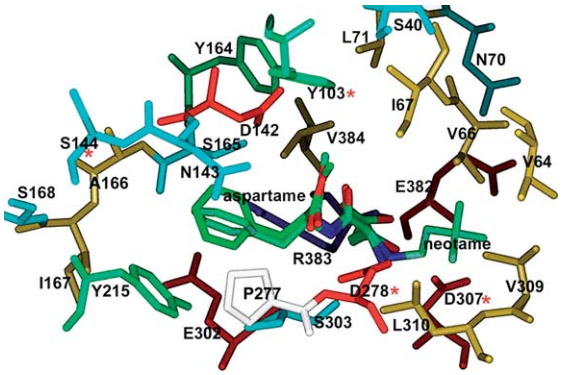

Figure 3 Model of cleft between lobes 1 and 2 of the venus flytrap module (VFTM) of hTas1R2 with docked aspartame and neotame. The metabotropic glutamate binding receptor (mGluR1; PDB:1EWK) crystal structure was used to model the VFTM of Tas1R2, then aspartame and neotame were individually docked onto the structure. Our model predicts that aspartame and neotame forms hydrogen bonds with the side chains of D278, D307, and S303, and makes hydrophobic interactions with the side chains of Y215, Y103, P277, and with the backbones of R383, V384, D142, and L279.

4.09.3.4.3 Mutational analysis of the aspartame interaction site within the venus flytrap module of hTas1R2

Our models of docked aspartame and neotame suggested that there is a good possibility that the VFTM of Tas1R2 contains a cleft between its lobes 1 and 2 that could serve as a small molecule-binding site for sugars and/or dipeptides akin to the canonical glutamate binding site of mGluR1. Using our identification of residues within the presumptive small molecule binding cleft of hTas1R2 we carried out alanine scan mutagenesis to determine which, if any, of residues do indeed contribute to a binding pocket for aspartame and other dipeptide sweeteners. In a few cases of interest (e.g., D307) we followed up with more conservative replacements. We have tested these mutants for their responses to aspartame and neotame (and cyclamate – our control for overall efficacy of mutant receptors) (Figure 4). Some mutations had similar effects on responsiveness to both aspartame and cyclamate (e.g., R383A, D307A, E302A, Y215A, D142A, and I67A), suggesting that they had altered general responsiveness of the receptor, or altered coupling between the VFTM of Tas1R2 and the TMD of Tas1R3. Other mutations had relatively specific effects on the response to aspartame (e.g., D307N, D278A, S144A, and Y103A), suggesting that they might be part of the aspartame-binding site. These residues are implicated by our model as being part of the binding site for aspartame within the VFTM of hTas1R2.

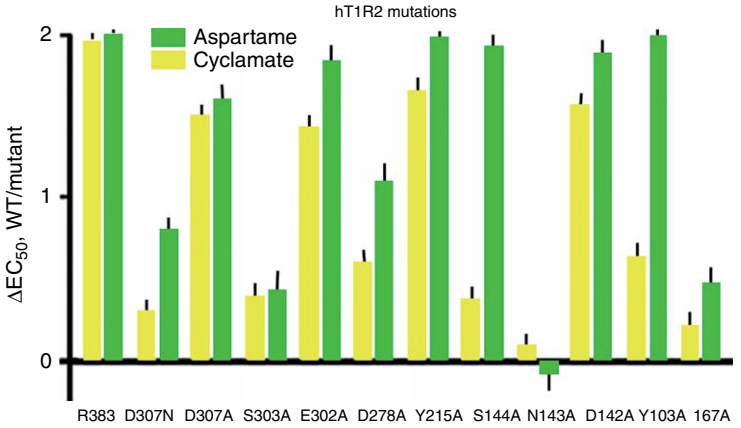

Figure 4 Effects of alanine scan mutations in the venus flytrap module (VFTM) of hTAS1R2 on responses to aspartame. Residues within a potential aspartame binding site of the VFTM of hTas1R2, predicted by homology with the metabotropic glutamate binding receptor binding site and by homology models of hTas1R2, were individually mutated to alanine (and in one case to asparagine (D307N)). Mutants were coexpressed with hTas1R3 and tested for responsiveness to aspartame and cyclamate. Some mutations had similar effects on responsiveness to both aspartame and cyclamate (e.g., R383A, D307A, E302A, Y215A, D142A, and I67A), suggesting that they altered general responsiveness of the receptor, or altered coupling between the VFTM of Tas1R2 and the TMD of TAS1R3. Other mutations had relatively specific effects on the response to aspartame (e.g., D307N, D278A, S144A, and Y103A), suggesting that they might be part of the aspartame binding site. ΔEC_{50}, the change in the effective concentration to produce 50% response; WT, wild type.

4.09.3.4.4 The expressed venus flytrap modules of both mTas1R2 and mTas1R3 bind sugars and sucralose

Work in Munger's laboratory, using direct physical binding assays, also shows that the expressed VFTMs of Tas1R2 and Tas1R3 react with sugars and sucralose as shown by changes in intrinsic fluorescence. The peak intrinsic tryptophan fluorescence of the mTas1R VFTM proteins was monitored and then the concentration–response relationship for this fluorescence was determined upon titration of VFTM with sweet ligands. Glucose, sucrose, and sucralose decreased the peak fluorescence intensity of $mTas1R3VFTM_{B6}$, exhibiting K_d values of 7.3 ± 0.7 mM, 2.9 ± 0.4 mM, and 0.9 ± 0.1 mM, respectively (Nie, Y. *et al.*, 2005), indicating binding of these ligands to the VFTM of mTas1R3. Ligand binding is known to stabilize a conformational change in the VFTMs of other class C GPCRs (Kunishima, N. *et al.*, 2000; Pin, J. P. *et al.*, 2003). A synchrotron radiation circular dichroism (SRCD) spectroscopy, assay was used to determine if Tas1R VFTMs undergo a ligand binding-dependent change in conformation. Addition of 5 mM glucose and sucrose were shown to produce large changes in the SRCD spectrum of the mTas1R2 and mTas1R3 VFTMs, although the changes seen differed between Tas1R2 and Tas1R3 VFTMs. These results demonstrate that the VFTMs of both Tas1R3 and Tas1R2 undergo a conformational change upon ligand binding, supporting roles for each subunit in response to binding sweet ligands. Using these two techniques, Nie Y. *et al.* (2005) showed that a naturally occurring variant in mouse Tas1R3 VFTM, *sac* (I60T), which renders the mice less sensitive to sweeteners was shown to alter the function of the sweet-taste receptor in two important ways: (1) by decreasing affinity for sweet ligands and (2) by inhibiting the subunit's ability to undergo a conformational change upon ligand binding. The diminished sweet preference displayed by nontaster mice is likely due to the decreased ability of Tas1R3 to bind ligand and/or undergo a conformational change that may be involved in signal transduction (Nie, Y. *et al.*, 2005).

4.09.3.4.5 The cysteine-rich domain of Tas1R3

In 2004 we determined that the CRD of hTas1R3 contains residues critical for the sweet receptor's interaction with the sweet protein brazzein (Jiang, P. *et al.*, 2004). Brazzein is sweet to humans, but not to mice. Using mismatched pairs and chimeric receptors from mouse and human, we identified a small region of the CRD of hTAS1R3 that was required for the response to brazzein (residues 535–545).

Within this region of the CRD of TAS1R3 there are only five amino acids that differ between mTAS1R3 and hTAS1R3 (see figure 3a of Jiang, P. *et al.*, 2004). Starting with hTAS1R3 we individually mutated each of these five amino acids to their mouse counterparts (a loss-of-function experiment; see figure 3b of Jiang, P. *et al.*, 2004). In this way we identified hTAS1R3 A537 and F540 as contributing to brazzein's activity. To identify additional residues of the CRD of hTAS1R3 involved in responsiveness to brazzein we made a series of alanine-scan mutations within the CRD (Jiang, P. *et al.*, personal communication). Analysis of these mutants showed that D535A selectively abolished sweet receptor responsiveness to brazzein (Figure 5). The adjacent substitution, D534A, had no effect on sweet receptor responses to brazzein or the other sweeteners in our panel. Substituting glutamine for aspartate at position 535 (D535Q) also blocked responsiveness to brazzein (Jiang, P. *et al.*, personal communication, data not shown).

A new crystal structure of mGluR3 that includes the CRD region was recently published (Muto, T. *et al.*, 2007). We have constructed a homology model of the heterotrimer hTas1R2 + hTas1R3 based on this new structure (Figure 6). In this structure we see that D535, A537, and F540 lie on a single face of the CRD, making it an attractive site of interaction for a site on brazzein. In addition, evidence suggests that brazzein also makes contact with the VFTM of Tas1R2, suggesting that this protein sweetener acts by stabilizing an active conformation of the receptor by binding to multiple domains simultaneously.

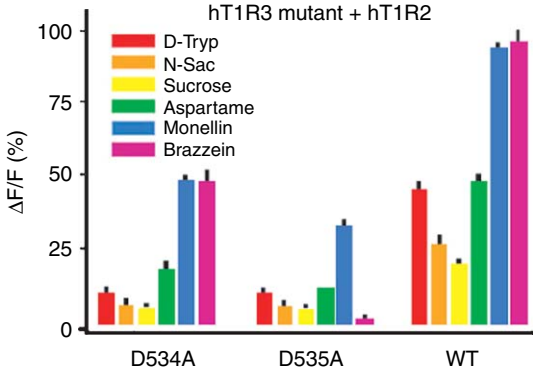

Figure 5 The D535A mutation in the cysteine-rich domain (CRD) of hTAS1R3 specifically abolishes sweet receptor responses to brazzein. Several residues within the CRD of hTas1R3 were individually mutated to alanine. Ala-scan mutants were coexpressed with hTas1R2 in HEK 293 cells along with a G-protein reporter, then tested for responsiveness to brazzein and a panel of sweeteners. D535A, but not D534A, showed a selective deficit in responsiveness to brazzein. D535 may participate in, or be close to the brazzein binding site in the CRD of hTas1R3.

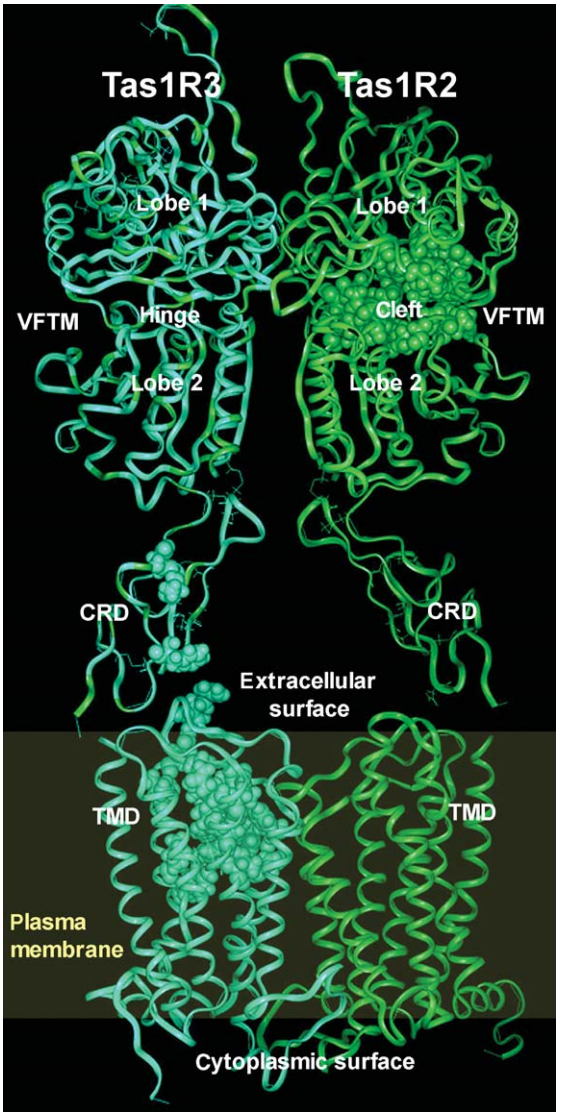

Figure 6 The homology model of all six domains of the sweet receptor (Tas1R2 + Tas1R3). The extracellular component of our model is based on the metabotropic glutamate binding receptor (mGluR3) venus flytrap module (VFTM) plus cysteine-rich domain (CRD) in the closed:closed configuration (2E4U). The two transmembrane domains are based on the crystal structure of rhodopsin (1HZX). The dimer interface between opposing helices 4 and 5 was chosen to best optimize the continuance of the CRD structure into that of TM helix 1 and is entirely speculative. The model is represented as a ribbon structure with only those residue side chains represented in Corey–Pauling–Koltun space filling representation. (CPK) that we have mutated and which alter receptor function in response to ligands. ΔF/F, the change of fluorescence at peak over the baseline fluorescence.

Other workers (Morini, G. *et al.*, 2005; Walters, D. E. and Hellekant, G., 2006) have independently used molecular modeling to dock the protein sweeteners, brazzein and monellin, to the open cleft of both Tas1R2 and Tas1R3 using a docking strategy that relies heavily on electrostatics as its primary basis for fitting ligand to binding site. It seems unlikely, however, that these protein sweeteners could activate the receptor by interacting with it in an open cleft conformation given the likelihood that the sweet receptor's mode of activation is similar to that of the mGluRs and calcium-sensing receptor which are known to require the closed state of the VFTM for activity.

4.09.3.4.6 The transmembrane domain of Tas1R3

The transmembrane portion of the sweet receptor is composed of one TMD from Tas1R2 and one from Tas1R3. It is presumed that these TMDs dimerize as has recently been shown for family A receptors although the specific contact interface(s) have yet to be determined. Like family A receptors, family C receptors have intra-TMD binding sites for small molecules that can act as either agonists or antagonists or as enhancers. From a series of human/mouse chimeras of Tas1R3 it was determined that it is the TMD of hTas1R3 that is required for sweet receptor responsiveness to cyclamate and lactisole (Jiang, P. *et al.*, 2005b; summarized in Figure 7). More refined chimeras and the generation of mutants (human-to-mouse loss of function and mouse-to-human gain of function) led us to identify specific residues within TM helices 5 (A733) and 7 (L798), and extracellular loop 3 (R790) that were required for the receptor to interact with cyclamate and lactisole.

These findings suggested that both lactisole and cyclamate bind within the TMD of the sweet receptor in a manner similar to that seen with other ligands binding to family A GPCRs (e.g., catecholamines bound within the TMD of the β-adrenergic receptor, or retinal bound within the TMD of rhodopsin). An alignment of the TMD of hTas1R3 with that of rhodopsin was used to identify 17 residues forming a candidate ligand-binding pocket within the TMD of hTas1R3. Alanine was substituted for each of these 17 residues and tested for responsiveness to a variety of sweeteners and lactisole. This produced seven receptors that responded to no tested sweetener, two receptors that were reduced specifically in their response to cyclamate, one receptor that was specifically reduced in their response to lactisole, and three receptors that had altered responsiveness to both cyclamate and lactisole. These results suggest that the binding pockets for cyclamate and latisole overlap within the TMD of hTas1R3 (Figure 8).

4.09.4 Future Studies/Unanswered Questions

Many questions remain to be answered about the sweet receptor. Of primary interest is mapping the various binding sites for ligands that lead to its active

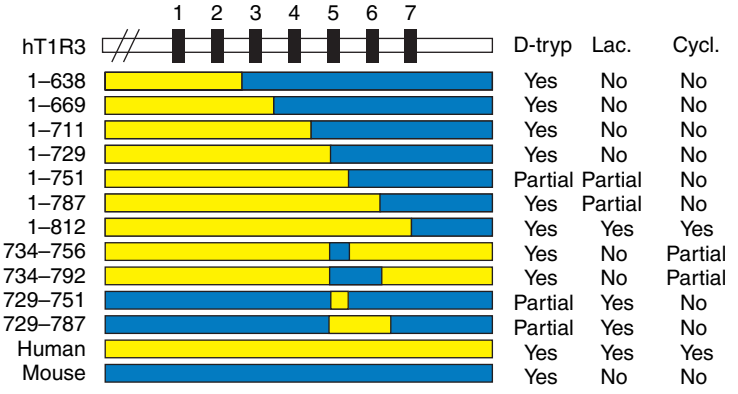

Figure 7 Schematic diagram showing responses of m/hTas1R3 chimeras to D-tryptophan, lactisole, and cyclamate. mTas1R3 portions are colored blue, hTas1R3 portions are yellow. Responsiveness of dimers of hTas1R2 + m/hTas1R3 chimeras to D-tryptophan (D-tryp), D-tryp + lactisole (Lac), or cyclamate (Cycl) are shown to the right. Chimeras containing mTas1R3 TM helix 5 did not respond to lactisole. The response to cyclamate by chimeras is more complicated and appears to require human residues in TM helices 5 and 7.

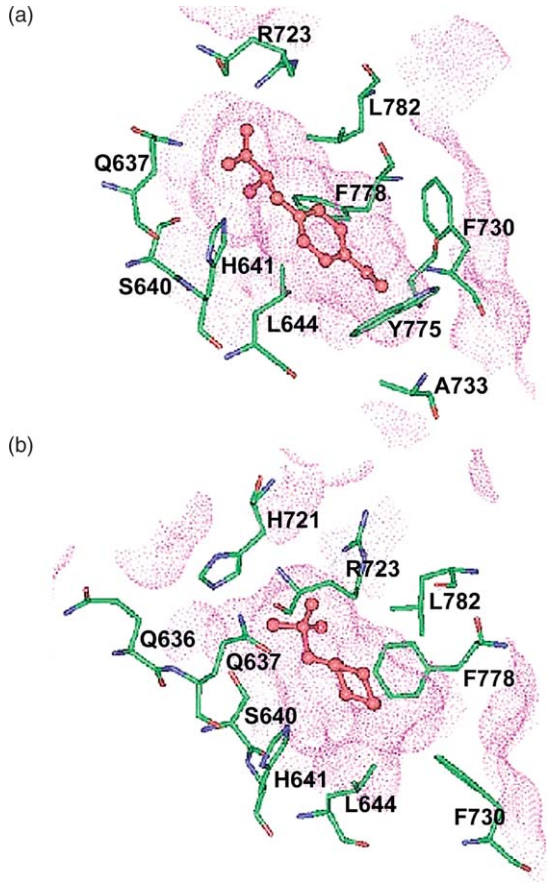

Figure 8 Models of the transmembrane domains (TMD) of the ligand-binding pocket of hTas1R3. (a) Lactisole docked within the TMD pocket. Lactisole's negatively charged propionic acid moiety is near H641 (TM helix 3). Lactisole's phenyl ring is predicted to form pi–pi interactions with F778 (TM helix 6). Lactisole's methoxyl group extends into a hydrophobic pocket and faces A733 (TM helix 5). (b) Cyclamate docked within the TMD pocket. The sulfamate group of cyclamate extends toward the top part of the pocket formed by TM helix 3 and extracellular loop 2. Residues Q637, S640, H641, H721, and R723 are in proximity to form ionic or hydrogen bonds with cyclamate's sulfamate group. Residues L644, F730, and F778 are predicted to form a hydrophobic pocket around cyclamate's cyclohexanyl group. Note that the binding pockets for the two ligands overlap but are not identical.

conformation. That there are over 50 molecules that taste sweet to humans that vary in structure from small molecule natural sugars, artificial sweeteners of multiple classes and even small proteins as well as at least one antagonist, suggests a great complexity to the receptor. Our work and that of others has demonstrated that there are multiple binding sites in at least four domains (VFTMs of Tas1R2 and Tas1R3 and the CRD and TMD of Tas1R3) and with overlapping binding sites for various ligands in each. New work from Jay Slack at Givaudan (personal communication, data not shown) suggests that the TMD of Tas1R2 may also be a binding site for perillartine (an aldoxime-type sweetener). An understanding of binding sites for sweeteners might well lead to a rational design for artificial sweeteners with better taste profiles. Binding-site studies along with investigations that use them to understand domain:domain interactions that lead to receptor activation may eventually give us the ability to rationally design better more potent sweeteners. Of even more interest, we might discover ways to enhance the sweetness of natural sugars with compounds that have no taste of their own.

An active area of investigation, not only of the sweet receptor but of all family C receptors is the conformational changes that the receptors undergo that leads to activation of G protein. Of particular interest is whether the monomer, the dimer or some larger grouping of receptors provides maximal activity in response to sweeteners. Of interest in this regard is the observation that many artificial sweeteners, while more potent than natural sugars, are none-the-less, at best, only partial agonists. Studies investigating additivity or synergy between sweeteners that bind to different domains of the receptor will be particularly important in our understanding of signal transmission within the sweet receptor.

Some of the knowledge gathered for sweet-taste receptors is still lacking for bitter-taste receptors. This applies in particular to the molecular architecture of TAS2Rs. Complex mutational analyses along with molecular modeling approaches are required. Clearly for a complete understanding of bitter-taste coding the cognate bitter substances for all TAS2Rs need to be identified, although this will be a never-ending project in light of the numerous bitter compounds and the extensive species differences. In humans, it emerges that there are pronounced variations among *TAS2R* genes, a fact that is expected to affect eating behavior. Uncovering the underlying mechanisms is scientifically interesting and of great potential medical and social importance for eating disorders, obesity, and their consequences. In this context, pharmacological treatment of taste in patients suffering from eating disorders with compounds developed by aid of *in vitro* receptor assay could be a therapeutic option. Another important

development in the field would be the elucidation of how bitter receptor cells communicate with the nervous system and how bitter transmission proceeds and is processed in relation to the other taste modalities. With some optimism we can await the future which will us bring exciting discoveries.

4.10.1 Introduction

During the past decade considerable progress has been made in revealing the basic mechanisms of taste transduction and signaling. This explosion of information is due in large part to the sequencing of the rodent and human genomes, allowing identification of the taste receptors, downstream signaling molecules, and effector ion channels involved in taste transduction. Further, these discoveries have led to the production of gene-targeted and transgenic mice, where the role of individual signaling proteins can be assessed *in vivo*. Here we review recent progress in quality-specific transduction, focusing primarily on mammalian taste cells. In addition, we discuss the identity and potential roles of neurotransmitters in taste cells and how taste information is communicated to afferent nerve fibers. Detailed information

about G-protein-coupled taste receptors (GPCRs) is covered in Chapter Taste Receptors.

4.10.1.1 Taste Qualities

The sense of taste affords organisms the ability to discriminate nutritionally important substances from potentially harmful ones. The gustatory system detects and discriminates nonvolatile stimuli representing five basic taste qualities – sweet, salty, sour, bitter, and umami. Sweet, salty, and umami stimuli are generally appetitive, because they represent chemicals required for proper nutrition. These include sugars for energy production, sodium (Na^+) for ionic homeostasis, and amino acids as a source for protein synthesis. Bitter and sour stimuli are naturally aversive and warn against ingestion of potentially toxic or poisonous substances.

Recently obtained evidence suggests that fat and water may each constitute additional primary taste qualities. In the case of fat, it is well established that mammals prefer lipid enriched foods. However, until recently, this preference for fat was presumed to be due only to its pleasant textural qualities (mouth feel). New data suggest that specific fatty acid receptors and fatty acid-modulated ion channels are expressed in taste receptor cells, where they may be involved in the detection of fatty acids as taste stimuli (for review, Laugerette, F. *et al.*, 2007). Similarly, water-permeable ion channels were recently found on the apical membrane of taste cells, suggesting they may be the source of the gustatory neural response to water (Watson, K. J. *et al.*, 2007). However, whether water represents a specific taste or whether it is involved in volume regulation of taste cells is not known.

4.10.1.2 Taste Buds, Taste Cell Types, and Afferent Innervation

Taste buds are the transducing elements of gustatory sensation. A typical taste bud is an onion shaped end organ comprising 50–100 spindle shaped cells that extend from the basal lamina to the surface of the tongue. The apical portion of each taste cell contains microvilli, which protrude through an opening in the epithelium called the taste pore. The basolateral membrane makes synaptic contacts with afferent nerve fibers, which project taste information to the brain. Four types of cells can be distinguished based on morphological and functional criteria. Type I cells, also known as dark cells, make up about 50% of the cells in a taste bud. These cells are generally considered to have a support function, and are not likely to be involved directly in transducing taste stimuli, although their apical membranes do reach the taste pore. The membranes of type I cells wrap around other cells in a glial-like fashion, and they express transporters and enzymes for uptake and inactivation of transmitters (Lawton, D. M. *et al.*, 2000; Bartel, D. L. *et al.*, 2006; Figure 1.) Type II cells, also known as light cells, make up about 30% of the taste bud. These cells express the taste receptors and downstream signaling elements implicated in responses to bitter, sweet, and umami taste stimuli. These cells associate with afferent nerve fibers, but do not form definitive synapses with pre- and postsynaptic specializations (Clapp, T. R. *et al.*, 2004; 2006). Type III cells, also known as intermediate cells, make up about 20% of cells in the

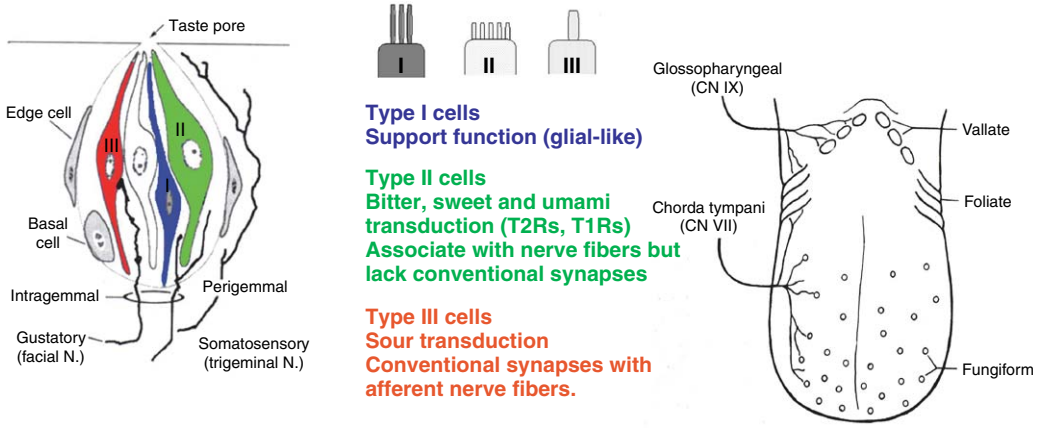

Figure 1 Cell types and innervation of taste buds. Type II taste cells are coded green, while Type III taste cells are coded red in subsequent figures. (Modified, with permission, from Finger and Simon, 2000).

taste bud. Recent evidence suggests that type III cells are the transducers of acidic (sour) stimuli (Richter, T. A. *et al.*, 2003; Kataoka, S. *et al.*, 2007). These cells form prominent synapses with afferent nerve fibers and may also be involved in cell-to-cell signaling in the taste bud (Herness, S. *et al.*, 2005; Roper, S. D., 2006). Proliferative basal cells are also found in the basolateral regions of the taste bud. These spherical cells divide to form new taste cells, which turn over every 10 days to 2 weeks. Ultrastructural features of these cell types are reviewed in Chapter Ultrastructure of Taste Buds.

Lingual taste buds are housed in connective tissue papillae. The anterior two-thirds of the tongue contains fungiform papillae, each of which contain one or two taste buds. These taste buds are innervated by the chorda tympani branch of the facial nerve (CN VII). The posterior region of the tongue contains the circumvallate and foliate papillae, each of which contain hundreds of taste buds. These taste buds are innervated primarily by the glossopharyngeal nerve (CN IX), but the anterior foliate taste buds are innervated by a branch of the chorda tympani nerve. Taste buds are also located on the soft palate, where they are innervated by the greater superficial petrosal nerve, a branch of CN VII, and on the larynx and esophagus, where they are innervated by a branch of the vagus nerve (CN X).

4.10.1.3 Taste Receptor Cell Properties

Simple taste stimuli, such as salts and acids, act on apically located ion channels, while more complex stimuli, such as sugars and plant alkaloids, bind to GPCRs and activate intracellular second messenger signaling cascades. In all cases, transduction appears to result in membrane depolarization and action potential initiation. Action potentials in taste cells were first observed over two decades ago, using intracellular recordings from mudpuppy taste cells (Roper, S., 1983). Action potentials are now known to be a general property of type II and type III rodent taste cells and they are generated regularly in response to most taste stimuli (Avenet, P. and Lindemann, B., 1991; Gilbertson, T. A. *et al.*, 1992; Cummings, T. A. *et al.*, 1993; Yoshida, R. *et al.*, 2006). Underlying action potential generation are tetrodotoxin-sensitive Na^+ channels (Herness, M. S. and Sun, X. D., 1995), a variety of potassium (K^+) channels (Chen, Y. *et al.*, 1996; Liu, L. *et al.*, 2005), and voltage-gated Ca^{2+} channels (Behe, P. *et al.*, 1990). Recent data obtained from specific taste cell types indicated that while both type II and type III cells express voltage-gated Na^+ and K^+ channels, only type III taste cells express voltage-gated Ca^{2+} channels (Medler, K. F. *et al.*, 2003; Clapp, T. R. *et al.*, 2006; DeFazio, R. A. *et al.*, 2006). The role of action potentials in the transduction process has been unclear, since taste cells are short receptor cells that should be capable of transmitter release without requiring action potentials. Recent data using cell attached recordings from a polarized, semi intact preparation show that the breadth of tuning of individual taste cells in response to taste stimuli is nearly identical to the breadth of tuning of single afferent nerve fibers, suggesting that action potentials may be required for transmitter release (Yoshida, R. *et al.*, 2006).

4.10.2 Quality Specific Transduction

During the past 10–15 years several candidate taste transduction elements have been identified in taste receptor cells. Validation of candidates as confirmed taste transduction elements requires their presence in taste cells along with the demonstration of their involvement, from *in vivo* and/or *in vitro* studies, in specific taste transduction pathways underlying particular taste qualities.

4.10.2.1 Salt Taste

Ingestion of salts, particularly NaCl, is critical for the maintenance of ionic homeostasis. The cation of the salt is the main component detected, and several cations, including Na^+, Li^+, K^+, Ca^{2+}, and NH_4^+ contribute to salty taste perception. When salts are present in sufficient concentration in the oral cavity, cations permeate ionic channels in the apical membrane of the taste cells, causing cationic influx and membrane depolarization. Monovalent cations also permeate the tight junctions at the apex of the taste bud, where they interact with the basolateral membrane of taste cells and generate a hyperpolarizing field potential (Ye, Q. *et al.*, 1991). This paracellular shunt pathway reduces the magnitude of the receptor potential and attenuates the perception of saltiness. The magnitude of the paracellular shunt is strongly influenced by the anion of the salt. Small anions such as chloride (Cl^-) diffuse readily into the paracellular space, where they blunt the hyperpolarizing field potential produced by the cations. In contrast, large anions such as gluconate and acetate fail to permeate the paracellular pathway. Thus, salts with large

anions are perceived to be less salty than equivalent concentrations of salts with small anions (Elliott, E. J. and Simon, S. A., 1990; Ye, Q. *et al.*, 1994).

4.10.2.1.1 Amiloride-sensitive versus amiloride-insensitive mechanisms

Salt taste transduction mechanisms vary in different species, depending on the ionic composition of the diet (Boudreau, J. C. *et al.*, 1985). Herbivores and other mammals on a low Na^+ diet have a Na^+-specific appetite, mediated by highly Na^+-specific channels that are inhibited by the diuretic drug amiloride. Amiloride-sensitive Na^+ channels were originally proposed as a salt transduction mechanism by John DeSimone and colleagues, who observed that the chorda tympani response to NaCl in rats is sensitive to amiloride (Heck, G. L. *et al.*, 1984). Whole cell patch-clamp studies have confirmed the presence of amiloride-sensitive Na^+ currents in hamster (Gilbertson, T. A. *et al.*, 1992; 1993; Gilbertson, T. A. and Fontenot, D. T., 1998), rat (Doolin, R. E. and Gilbertson, T. A., 1996), and mouse (Miyamoto, T. *et al.*, 2001) fungiform taste cells. However, other mechanisms for salt transduction exist, because about 20% of the chorda tympani response and the entire glossopharyngeal response to NaCl is amiloride-insensitive in rodents (Ninomiya, Y. *et al.*, 1989; Gannon, K. S. and Contreras, R. J., 1995; Ninomiya, Y., 1998). Amiloride-insensitive mechanisms appear to predominate in species with adequate dietary Na^+ levels, including humans, although both mechanisms exist to some extent in most species. While amiloride-sensitive mechanisms are highly Na^+ selective, amiloride-insensitive mechanisms do not discriminate between cations. Indeed, when the chorda tympani nerve is transected, or when amiloride is present, rats lose the ability to discriminate Na^+ from K^+ in behavioral discrimination assays (Spector, A. C. *et al.*, 1996). Amiloride-sensitive and -insensitive mechanisms are likely distributed in different taste cells, because NaCl responses in single chorda tympani nerve fibers are either inhibited completely by amiloride, or unaffected by amiloride (Figure 2). Fibers that are inhibited by amiloride are narrowly tuned to NaCl (i.e., N fibers), while amiloride-insensitive fibers are broadly tuned to several salts as well as acids (i.e., H fibers; for a recent review, see Spector, A. C. and Travers, S. P., 2005).

4.10.2.1.2 ENaC – the amiloride-sensitive salt taste receptor

The epithelial Na^+ channel ENaC is now believed to be the Na^+-specific, amiloride-sensitive salt taste receptor. ENaC was first cloned from colon epithelium, but is expressed widely in many Na^+-transporting epithelial tissues (for review, see Garty, H. and Palmer, L. G., 1997). The functional channel is composed of three homologous subunits, α, β, and γ. Expression studies in heterologous cells suggest that all three subunits are required for normal function (Canessa, C. M. *et al.*, 1994). In taste cells,

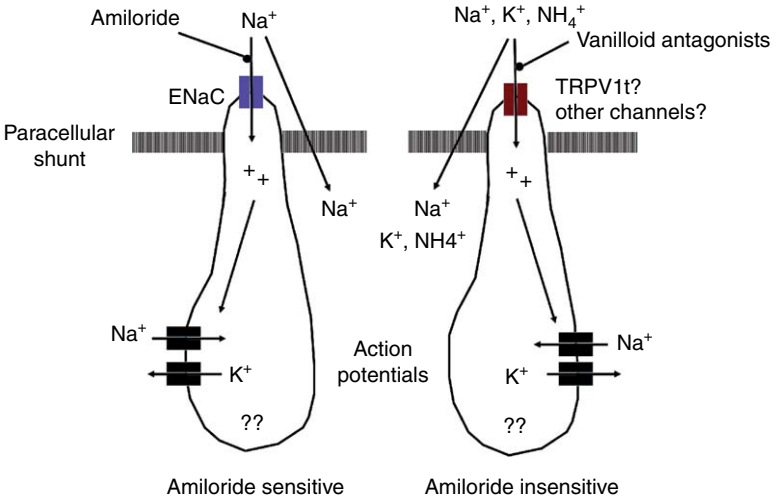

Figure 2 Salt transduction. The epithelial Na^+ channel ENaC is the amiloride-sensitive, Na^+ specific salt taste receptor. Other apical channels, including a variant of the capsaicin receptor TRPV1, mediate the amiloride-insensitive salt response, which is non-selective for cations. These mechanisms appear to be expressed in different populations of taste cells, but in neither case is it clear which taste cell type (II or III) mediates the response.

molecular and immunocytochemical studies indicate that α-, β-, and γ-ENaC are expressed in a large fraction of rat taste cells in all papilla. However, the density of expression of β- and γ-ENaC is significantly lower in foliate and circumvallate taste cells compared to fungiform taste cells (Kretz, O. *et al.*, 1999; Lin, W. *et al.*, 1999). This differential expression is consistent with the presence of functional amiloride-sensitive Na^+ currents in fungiform, but not in vallate or foliate taste cells (Doolin, R. E. and Gilbertson, T. A., 1996). ENaC in taste cells shares electrophysiological and pharmacological properties with ENaC in other tissues, including a high sensitivity to amiloride, high selectivity for Na^+ over K^+, significant permeability to protons, and self-inhibition by extracellular Na^+ (Gilbertson, T. A. *et al.*, 1993; Doolin, R. E. and Gilbertson, T. A., 1996; Gilbertson, T. A. and Zhang, H., 1998). Further, the same hormones that regulate Na^+ transport in epithelial cells regulate ENaC expression in taste cells. Both aldosterone and vasopressin increase the number of functional channels in the apical membrane (Herness, M. S., 1992; Gilbertson, T. A. *et al.*, 1993; Lin, W. *et al.*, 1999), while atrial natriuretic peptide (ANP) and oxytocin decrease them (Lindemann, B. *et al.*, 1999). Vasopressin acts via the V_2 receptor to increase the density of existing channels, probably via cAMP-dependent phosphorylation, while aldosterone likely acts to increase transcription of the channel, as it does in other tissues. Interestingly, aldosterone treatment of rats causes upregulation of both β- and γ-ENaC in taste cells, resulting in a larger density of amiloride-sensitive currents in fungiform taste cells. In vallate and foliate taste cells, which are normally unresponsive to amiloride, aldosterone treatment induces a small amiloride-sensitive Na^+ current in about half of the taste cells (Lin, W. *et al.*, 1999).

4.10.2.1.3 Amiloride-insensitive mechanisms

In contrast to the amiloride-sensitive mechanism, much less is known about the basis of amiloride-insensitive salt mechanisms, and multiple mechanisms are likely to contribute. The amiloride-insensitive mechanism was originally believed to be solely a consequence of the paracellular shunt pathway. Na^+ and other monovalent cations penetrate the tight junctions and come into contract with the basolateral membrane of taste cells. However, amiloride is impermeable and therefore inaccessible to basolateral Na^+ channels. Although ENaC channels are restricted to the apical membrane in most transporting epithelia, some studies have suggested basolateral amiloride-sensitive Na^+ channels are present in taste cells. Ussing chamber studies in rat showed that amiloride inhibited a Na^+ current in the basolateral regions of taste epithelia, but these channels were less sensitive to amiloride than were apical channels ($K_i = 52\,\mu M$ compared to $0.2\,\mu M$), and less highly selective for Na^+ (Mierson, S. *et al.*, 1996). Whether this mechanism contributes significantly to the amiloride-insensitive Na^+ response is not clear. The concentration of Na^+ in the extracellular space near taste cells is at least 140 mM, and it is difficult to conceive how salt taste stimuli could achieve sufficient concentrations in the paracellular space to create a driving force for Na^+ to enter the cells.

Recent studies suggest that, in addition to the paracellular pathway, apical nonselective cation channels may contribute to the amiloride-insensitive mechanism. Evidence for apical nonselective cation channels was first obtained from whole cell recordings in polarized mouse taste cells, where apical NaCl stimulation was shown to elicit both amiloride-sensitive and amiloride-insensitive inward currents (Miyamoto, T. *et al.*, 2001). Further evidence for apical nonselective cation channels was obtained by the use of a novel pharmacological probe, cetylpyridinium chloride (CPC). When applied to the rat tongue, CPC selectively modulates the amiloride-insensitive component of the chorda tympani response to NaCl as well as responses to KCl and NH_4Cl, suggesting that the conductance may be a nonselective cation channel (Lyall, V. *et al.*, 2001). CPC is chemically related to the vanilloid family of modulators, which suggested that the channel may be related to the vanilloid family of TRP channels, the TRPVs. Indeed, a variant of TRPV1, called TRPV1t, is expressed in fungiform taste receptor cells (Lyall, V. *et al.*, 2004b). Several lines of evidence suggested a role of TRPV1t in the amiloride-insensitive salt response. First, other vanilloid modulators, including resiniferatoxin and capsaicin, selectively modulate the amiloride-insensitive chorda tympani response, and the response is temperature-sensitive, as is characteristic of TRPV channels. Further, blockers of TRPV1, including capsazepine and SB-366791, inhibit the amiloride-insensitive response. Finally, TRPV1 knockout mice appear to be lack the amiloride-insensitive chorda tympani response to NaCl (Lyall, V. *et al.*, 2004b). However, a more detailed analysis of chorda tympani responses in the knockout mice revealed that although the tonic portion of the

amiloride-insensitive salt response is missing, some phasic response remains in the knockout (Treesukosol, Y. *et al.*, 2007). Further, behavioral studies revealed nearly identical detection thresholds for NaCl in knockout and wild-type mice, even in the presence of amiloride (Ruiz, C. *et al.*, 2006; Treesukosol, Y. *et al.*, 2007). Two bottle preference tests showed that TRPV1 knockout mice prefer NaCl at concentrations normally avoided by wild-type mice, suggesting that TRPV1t may play a role in the avoidance of high concentrations of salt (Ruiz, C. *et al.*, 2006), but this must be confirmed with brief access tests to rule out post ingestive effects. What these behavioral data imply is that additional mechanisms must contribute to the amiloride-insensitive salt response. Further studies are needed, particularly on circumvallate and foliate taste buds, where the amiloride-insensitive response predominates.

4.10.2.2 Sour Taste

Acidic stimuli elicit sour taste, a naturally aversive taste quality that likely evolved to prevent ingestion of strong acids, spoiled foods, and unripe fruit. As is the case with salt transduction, sour taste transduction mechanisms likely involve both apical and paracellular pathways, and mechanisms vary considerably in different species. Generally, however, weak organic acids produce larger nerve responses and taste more sour than strong highly dissociated acids at equivalent pH (for recent review, see DeSimone, J. A. and Lyall, V., 2006). Thus, extracellular protons are unlikely to be the effective stimulus in sour transduction.

4.10.2.2.1 Intracellular versus extracellular pH as a stimulus

A preponderance of data suggests that intracellular pH (pH_i), is the proximate stimulus mediating sour taste transduction. Similar concentrations of buffered and unbuffered acids produce equivalent chorda tympani nerve responses and equivalent decreases in pH_i, even though their pH_o levels are vastly different. Direct evidence for the role of intracellular pH in sour transduction was obtained recently by exposing the rat tongue to nigericin, a K^+-H^+ exchanger that equilibrates pH_i with pH_o when high extracellular K^+ is present. Under these conditions, intracellular pH can be controlled rather precisely simply by varying the pH of extracellular solution. In the presence of nigericin and K^+, the threshold for eliciting a chorda tympani response decreases from pH 4.5 to pH 6.5 (Lyall, V. *et al.*, 2007). It is proposed that neutral acids, such as citric or acetic acid readily permeate the plasma membrane of taste cells in their undissociated form. Once inside the cell they dissociate, resulting in a decreased pH_i (Lyall, V. *et al.*, 2001). CO_2 also readily crosses the membrane, where it is converted intracellularly to H_2CO_3 by carbonic anhydrase. Strong acids also decrease intracellular pH, likely by permeation of proton channels, but lower pH values are required for equivalent effects. In addition to proton permeable channels, several proton-modulated ion channels are expressed in taste cells and these may also contribute to sour transduction, by depolarizing taste cells and activating voltage-gated Ca^{2+} channels. The identity of channels proposed to be involved in sour taste is summarized below.

4.10.2.2.2 Proton-permeable ion channels

In mice and rats, evidence exists for two types of apical proton channels. The chorda tympani response to HCl, but not to weak acids or CO_2, is decreased by several proton channel blockers, including Zn^{2+}, Cd^{2+} and diethylpolycarbonate (DEPC; DeSimone, J. A. *et al.*, 2007). The pharmacology of the response suggests that the proton influx may occur via the NADPH oxidase-linked proton channel, $gp91^{phox}$. This hypothesis was recently tested with $gp91^{phox}$ knockout mice, in which approximately 60% of the chorda tympani response to HCl was diminished. The remaining response was insensitive to specific modulators of $gp91^{phox}$, but was enhanced by membrane permeant analogs of cAMP (Lyall, V. *et al.*, 2002; DeSimone, J. A. *et al.*, 2007). The identity of the cAMP-modulated proton channel is not known.

The epithelial Na channel ENaC is also permeable to H^+ in the absence of extracellular Na^+. In hamsters, where salivary Na^+ is very low, ENaC appears to contribute to sour transduction (Gilbertson, T. A. *et al.*, 1992; 1993; Gilbertson, D. M. and Gilbertson, T. A., 1994). However, amiloride has no effect on acid responses in mice (Miyamoto, T. *et al.*, 2000; Richter, T. A. *et al.*, 2003) or rats (DeSimone, J. A. *et al.*, 1995), suggesting that this mechanism may be unique to hamsters.

4.10.2.2.3 Proton-gated ion channels

A number of proton-gated cation channels are expressed in taste cells and several have been suggested to serve as sour receptors or modulators. However, none is known definitively to contribute to sour transduction *in vivo*. Acid-sensing ion channels (ASICs), which are proton-gated cation channels that mediate pain perception accompanying tissue acidosis

(Waldmann, R. *et al.*, 1999), have been proposed as sour receptors. ASIC2a and 2b are co-expressed in many rat taste cells (Ugawa, S. *et al.*, 1998; 2003), and when heterologously expressed, the channels mediate a transient, amiloride-sensitive inward current in response to a decrease in extracellular pH. In a subset of isolated rat taste cells, pH 4.5 similarly elicits a transient inward current that is partially sensitive to high concentrations of amiloride (Lin, W. *et al.*, 2002). However, ASIC2 knockout mice have normal behavioral and electrophysiological responses to low pH, suggesting that the acid-gated inward current is likely mediated by a different mechanism, at least in mice (Kinnamon, S. C. *et al.*, 2000; Richter, T. A. *et al.*, 2004b). Again, species differences may be involved here, since much less ASIC2 mRNA is present in mouse taste cells compared to those of rat (Richter, T. A. *et al.*, 2004b).

The hyperpolarization-activated channels HCN1 and HCN4 are expressed in a subset of rat taste cells. These channels were suggested to serve as sour receptors, because, when expressed in heterologous cells, they are activated by low external pH (Stevens, D. R. *et al.*, 2001). However, Cs^+, a specific blocker of HCN channels, has no effect on acid-induced Ca^{2+} responses in mouse taste cells (Richter, T. A. *et al.*, 2003), suggesting that HCN channels may play other roles in the taste bud.

In polarized mouse taste cells, apically applied citric acid elicits an inward current that is sensitive to NPPB, a Cl^- channel blocker (Miyamoto, T. *et al.*, 1998). These data suggest that an acid-gated Cl^- channel may be involved in sour transduction. Two acid-sensitive Cl^- channels have been identified in taste cells, CIC-4 and its splice variant, CIC-4A (Huang, L. *et al.*, 2005). Whether either of these channels is directly involved in acid detection remains to be determined.

4.10.2.2.4 Proton-blocked K^+ channels

Most K^+ channels are inhibited by a decrease in pH_o. K^+ channel block could conceivably contribute to acid-induced depolarization, if the K^+ channels were localized to the apical membrane and conductive at the resting potential. In mudpuppy, voltage-gated K^+ channels are restricted to the apical membrane, where they are blocked directly by protons to depolarize the membrane (Kinnamon, S. C. *et al.*, 1988; Roper, S. D. and McBride, D. W., Jr., 1989). However, in mammals, several studies have indicated that K^+ channels appear to be absent from the apical membrane, at least in fungiform taste cells (Miyamoto, T. *et al.*, 1996; Furue, H. and Yoshii, K., 1997; Miyamoto, T. *et al.*, 1998). Thus, this mechanism is unlikely to contribute to sour transduction in mammals. Basolateral K^+ channels could contribute to sour transduction, if they are inhibited by a decrease in intracellular pH. Several members of the two-pore domain K^+ channels (K_{2P} or KCNK) are expressed in rat taste cells, including TWIK 1, TASK 1-2, TREK 1-2, and TRAAK 1 (Lin, W. *et al.*, 2004; Richter, T. A. *et al.*, 2004a). Some of these channels can be modulated by intracellular acidification, however whether they are located in the taste cells that communicate sour information to the nervous system is unknown.

4.10.2.2.5 PKD1L3 and PKD2L1

Recently, two members of the TRPP family of transient receptor potential (TRP) channels, PKD1L3 and PKD2L1, were identified in taste cells by expression screening. These channels are expressed in a specific subset of taste cells, distinct from the type II taste cells involved in bitter, sweet, and umami transduction (Huang, A. L. *et al.*, 2006; Ishimaru, Y. *et al.*, 2006; LopezJimenez, N. D. *et al.*, 2006). When coexpressed in heterologous cells, PKD2L1 and PKD1L3 respond to low pH_o with an increase in intracellular Ca^{2+}. The increase in intracellular Ca^{2+} occurs with a delay, suggesting that intracellular, rather than extracellular pH may be mediating the effect (Ishimaru, Y. *et al.*, 2006). Recent immunocytochemical studies using antibodies directed against PKD2L1 show that although the channel is located in the apical third of the taste bud, most channels appear to be located basolateral to the tight junctions, where they would be more likely to respond to changes in intracellular pH. Further, the channel is expressed exclusively in the type III taste cells, those cells that express voltage-gated Ca^{2+} channels (Kataoka, S. *et al.*, 2007). These data agree well with Richter T. A. *et al.* (2003), who show that apically applied acids elicit a decrease in intracellular pH in most taste cells, but only those taste cells with voltage-gated Ca^{2+} channels show a concomitant increase in intracellular Ca^{2+} (Richter, T. A. *et al.*, 2003). These data suggest that the taste cells with voltage-gated Ca^{2+} channels are the cells that communicate sour taste information to the nervous system.

Further evidence for a role of PKD channels in sour taste came from molecular studies of the Zuker laboratory. Targeted expression of diphtheria toxin (DTA) was used to ablate those taste cells which expressed PKD2L1. These mice completely lack chorda tympani responses to all acids, both weak and strong, but have normal responses to other taste

stimuli (Huang, A. L. *et al.*, 2006). These data suggest that the same taste cells transduce both strong and weak acids, and that the sour transducing taste cells are likely to be a unique subset of taste cells. However, PKD channel knockouts will be needed to determine if any of the PKD proteins are involved in sour transduction (Figure 3).

4.10.2.2.6 Downstream signaling effectors in sour taste

The DeSimone laboratory has combined single cell imaging with chorda tympani nerve recording to investigate sour transduction downstream of the decrease in intracellular pH (for review, DeSimone, J. A. and Lyall, V., 2006). They have found that the phasic part of the chorda tympani response to both strong and weak acids is mediated by different mechanisms than is the tonic portion of the response. The phasic part of the response is associated with a rapid, pH_i-mediated decrease in taste cell volume, caused by a change in the equilibrium between F-actin and G-actin. This in turn activates a flufenamic acid-sensitive shrinkage-activated cation channel on the basolateral membrane. Blocking either the conversion of F-actin to G-actin, or the cation channel completely suppresses the phasic portion of the chorda tympani, with no effect on the tonic portion of the response (Lyall, V. *et al.*, 2006). In contrast, the tonic portion of the response appears to be Ca^{2+}-dependent. It is likely that the decrease in pH_i activates a cation channel, possibly PKD2L1, which results in membrane depolarization and activation of voltage-gated Ca^{2+} channels, mediating transmitter release. The increase in intracellular Ca^{2+} not only mediates the tonic part of the chorda tympani response to acids but also causes adaptation to acids, by activating a basolateral Na^+-H^+ exchanger, NHE1 (Lyall, V. *et al.*, 2004a; Vinnikova, A. K. *et al.*, 2004). This exchanger likely attenuates the decrease in pH_i, which would cause adaptation of the inward induced by acid stimulation. Indeed, acid stimulation induces a rapidly adapting current in taste cells (Lin, W. *et al.*, 2002), but further studies will be required to determine if the adaptation phase is dependent on NHE1.

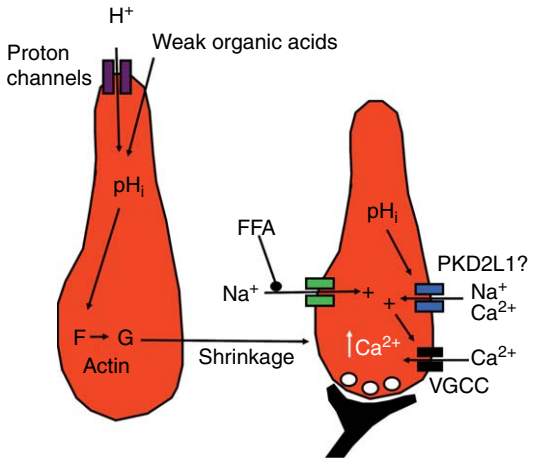

Figure 3 Sour transduction. Proton channels mediate the response to strong acids, while weak organic acids permeate the cell membrane in the undissociated state. Both mechanisms are present in the same taste cells, and both lead to decreases in intracellular pH, which is the proximate stimulus for sour transduction. The decrease in pHi leads to a change in the equilibrium between F and G actin, causing the taste cell to shrink in volume. The shrinkage activates a flufenamic-sensitive cation channel, which elicits the phasic portion of the afferent nerve response. The tonic portion of the nerve response is also mediated by the decrease in pHi, which activates a proton-gated non-selective cation channel, possibly PKD2L1. This causes membrane depolarization and activation of voltage-gated Ca^{2+} channels, presumably in Type III taste cells, since these are the only taste cells that express voltage gated Ca^{2+} channels.

4.10.2.3 Transduction Mechanisms Common to Bitter, Sweet, and Umami Taste Qualities

Although different GPCRs have been shown to underlie the initial detection of bitter, sweet and umami tastants (see Chapter Taste Receptors), there are several transduction elements that are common to pathways underlying all three taste qualities. As is typical of signaling pathways in sensory and nonsensory systems, specific GPCRs couple through their associated G proteins to initiate signaling cascades involving effector enzymes, second messengers and second messenger-activated/inhibited ion channels and other end targets.

4.10.2.3.1 G proteins

The first taste signaling element identified was α-gustducin, an α-transducin-like G protein α-subunit selectively expressed in ~25% of taste cells, specifically of type II (McLaughlin, S. K. *et al.*, 1992; Boughter, J. D., Jr. *et al.*, 1997). In *in vitro* assays gustducin heterotrimers couple to isolated native bitter receptors (Ruiz-Avila, L. *et al.*, 2000) and heterologously expressed bitter-responsive T2R receptors (Chandrashekar, J. *et al.*, 2000). Heterotrimers containing α-gustducin chimeras

capable of promoting calcium mobilization (to monitor receptor activity) also couple to heterologously expressed sweet-responsive T1R2 + T1R3 receptors and umami-responsive T1R1 + T1R3 receptors (Nelson, G. *et al.*, 2001; Li, X. *et al.*, 2002; Nelson, G. *et al.*, 2002). Studies of α-gustducin knockout mice have demonstrated gustducin's key role *in vivo* in bitter, sweet and umami taste transduction (Wong, G. T. *et al.*, 1996; Ming, D. *et al.*, 1998; Ruiz-Avila, L. *et al.*, 2001; Ruiz, C. J. *et al.*, 2003; Glendinning, J. I. *et al.*, 2005; Danilova, V. *et al.*, 2006). That α-gustducin knockout mice have markedly reduced, but not entirely absent, behavioral and nerve responses to the bitter, sweet and umami compounds suggests that other taste cell-expressed G proteins may couple to these GPCRs normally or in the absence of gustducin. Consistent with this inference is the observation that transgenic expression of a dominant-negative version of α-gustducin in the α-gustducin knockout background further diminished taste responses to bitter and sweet (Ruiz-Avila, L. *et al.*, 2001).

In addition to α-gustducin the following G α-subunits are known to be expressed in taste cells: Gαs, Gαq, Gα14, Gα15, Gαi2, Gαi3, α-transducin (McLaughlin, S. K. *et al.*, 1992; Ruiz-Avila, L. *et al.*, 1995; Boughter, J. D., Jr. *et al.*, 1997; Kusakabe, Y. *et al.*, 1998). Heterologously expressed mT2R5 selectively coupled to α-gustducin over the other G proteins examined (αi, αs, αo, or αq) (Chandrashekar, J. *et al.*, 2000). Although α-transducin knockouts had no effect on taste responses, double knockouts lacking α-transducin and α-gustducin showed that α-transducin is involved in umami taste, but not in bitter or sweet (He, W. *et al.*, 2004).

Upon activation, heterotrimeric G proteins such as gustducin dissociate into α and $\beta\gamma$ components, each capable of carrying a signal to one or more downstream effectors. Gβ1, Gβ3, and Gγ13 are expressed with α-gustducin and Gαi2 in type II taste cells (Huang, L. *et al.*, 1999; Clapp, T. R. *et al.*, 2001). α-Gustducin expressing taste cells are a subset of those which express Gγ13 and Gαi2 (Huang, L. *et al.*, 1999; Adler, E. *et al.*, 2000; Matsunami, H. *et al.*, 2000; Clapp, T. R. *et al.*, 2001). The T2R bitter receptors are only expressed in a subset of gustducin-positive type II taste cells (Adler, E. *et al.*, 2000; Matsunami, H. *et al.*, 2000; Kim, M. R. *et al.*, 2003) and likely couple preferentially to gustducin over any other G proteins in those same taste cells. Marked regional differences in coexpression of gustducin and taste receptors have been noted: in posterior fields (i.e., circumvallate papillae) gustducin was typically found along with T2Rs, while in anterior fields (fungiform papillae and palatal taste buds) gustducin is more often seen coexpressed with T1Rs (Huang, L. *et al.*, 1999; Adler, E. *et al.*, 2000; Matsunami, H. *et al.*, 2000; Clapp, T. R. *et al.*, 2001; Stone, L. M. *et al.*, 2007). This pattern is consistent with gustducin's involvement in responses to bitter, sweet, and umami taste stimuli.

4.10.2.3.2 Effector enzymes

Phospholipase β2 (PLCβ2), phospholipase A2, cNMP phosphodiesterase (PDE), and adenylyl cyclase (AC) type 8 have been identified in type II taste cells as candidate effector enzymes to mediate G protein-dependent taste responses (Ruiz-Avila, L. *et al.*, 1995; Rossler, P. *et al.*, 1998; Oike, H. *et al.*, 2006a; Trubey, K. R. *et al.*, 2006). α-Gustducin and α-transducin activate retinal and taste PDEs (Ruiz-Avila, L. *et al.*, 1995), whereas gustducin's $\beta\gamma$ complex activates taste PLCβ2 (Huang, L. *et al.*, 1999; Matsunami, H. *et al.*, 2000; Yan, W. *et al.*, 2001). In *in vitro* assays antibodies against α-gustducin, but not those against gustducin's β subunits, blocked stimulation of taste tissue PDE activity by native bitter taste receptors (Yan, W. *et al.*, 2001). Conversely, antibodies against Gβ3 or Gγ13 blocked the IP_3 response of taste tissue receptors to bitters, but had no effect on cNMP levels (Huang, L. *et al.*, 1999; Yan, W. *et al.*, 2001). Thus, heterotrimeric gustducin interacts with two different effectors to effect two responses in taste cells: 1. hydrolysis of cNMPs via α-subunit activation of PDE, and 2. generation of IP_3 and DAG via $\beta\gamma$ activation of PLCβ2. The subsequent steps in the PLCβ2 pathway are activation of IP_3 receptors (type III IP_3 receptors are selectively expressed in the same type II taste cells that express PLCβ2 (Clapp, T. R. *et al.*, 2001) and release of Ca^{2+} from internal stores followed by activation of the calcium-activated cation channel Trpm5 (see below). Arachidonic acid generated by taste cell-expressed phospholipase A2 (Oike, H. *et al.*, 2006a) may activate Trpm5 (Oike, H. *et al.*, 2006b). The subsequent steps in the cNMP pathway are presently unclear: decreased cNMPs may act on protein kinases which in turn may regulate taste cell ion channel activity, or cNMP levels may regulate directly the activity of cNMP-gated and cNMP-inhibited ion channels expressed in taste cells (Kolesnikov, S. S. and Margolskee, R. F., 1995; Misaka, T. *et al.*, 1997; 1998; 1999).

Both PLCβ2 and AC have been implicated in sweet taste transduction (reviewed in (Kinnamon, S.

C. and Margolskee, R. F., 1996; Lindemann, B., 1996; Herness, M. S. and Gilbertson, T. A., 1999). In both biochemical and physiological studies taste responses to sugars differ from those to artificial sweeteners. In biochemical studies with taste tissue, sucrose elicits an elevation of cAMP, while certain artificial sweeteners lead to the generation of IP_3 (reviewed in Kinnamon, S. C. and Margolskee, R. F., 1996; Lindemann, B., 1996; Herness, M. S. and Gilbertson, T. A., 1999). In physiological studies with rat taste cells, sucrose led to Ca^{2+} influx, while the artificial sweeteners saccharin and SC45647 elevated Ca^{2+} via release from internal stores (Bernhardt, S. J. *et al.*, 1996). Although a single heterodimeric sweet receptor (T1R2 + T1R3) mediates responses to both natural and artificial sweeteners (see Chapter Taste Receptors), it appears that activation by different types of sweet compounds elicits differential activation of downstream effectors, presumably by promoting activation of one or another G protein coupled to the sweet receptor.

4.10.2.3.3 PLCβ2 knockout mice

PLCβ2 knockout mice were reported to lack all nerve and behavioral responses to bitter, sweet and umami compounds (Zhang, Y. *et al.*, 2003; Damak, S. *et al.*, 2006). In a subsequent behavioral study it was shown that these knockout mice displayed aversive responses to high concentrations of the bitter compounds quinine and denatonium (Dotson, C. D. *et al.*, 2005). Although the PLCβ2 knockout mice showed no appetitive lick responses to sucrose at even the highest concentrations, their aversive responses to high concentrations of bitters were shifted to about a tenfold higher threshold (Dotson, C. D. *et al.*, 2005). This indicates that at least for bitters there are PLCβ2-independent mechanisms that come to bear at high concentrations.

4.10.2.3.4 Target channels

Trpm5 is a transient receptor potential ion channel subtype that is selectively expressed in type II taste cells along with α-gustducin, Gγ13 and PLCβ2 (Clapp, T. R. *et al.*, 2001; Perez, C. A. *et al.*, 2002). Trpm5 is cation selective and in heterologous expression systems can be activated by IP_3 or intracellular Ca^{2+} (Hofmann, T. *et al.*, 2003; Liu, D. and Liman, E. R., 2003; Prawitt, D. *et al.*, 2003) or arachidonic acid (Oike, H. *et al.*, 2006b). Recent studies with caged IP_3 and caged Ca^{2+} show that native Trpm5 in excised taste cell patches is gated directly by Ca^{2+} (Zhang, Y. *et al.*, 2007). Similarly to PLCβ2 knockout mice, Trpm5 knockout mice have pronounced deficits in their nerve and behavioral responses to bitter, sweet and umami compounds (Zhang, Y. *et al.*, 2003; Damak, S. *et al.*, 2006). However, Trpm5-independent transduction mechanisms contributing to bitter, sweet and umami were revealed by the reduced but not absent nerve and behavioral responses observed with Trpm5 knockout mice (Damak, S. *et al.*, 2006; Figure 4). It was noted that the effects of knocking

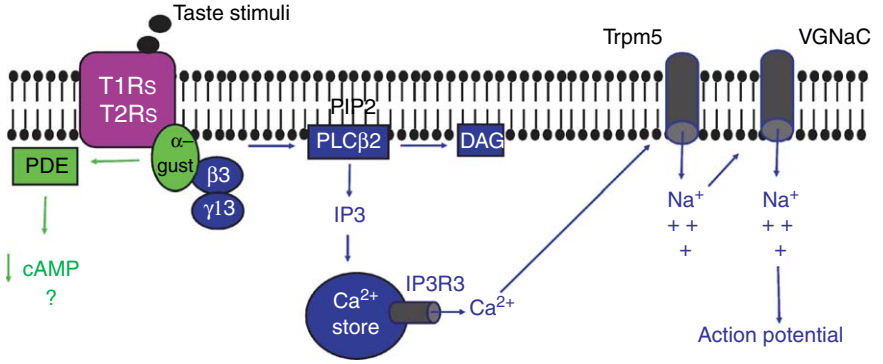

Figure 4 Transduction of bitter, sweet, and umami taste stimuli. Although different receptors are involved (T2Rs for bitter and T1Rs for sweet and umami stimuli), all utilize similar downstream signaling effectors in Type II taste cells. Receptor binding leads to activation of a heterotrimeric G protein, gustducin. The α subunit activates phosphodiesterase (PDE) to decrease intracellular cAMP, while the $\beta\gamma$ partners stimulate phospholipase Cβ2 (PLCβ2) to produce the second messengers IP3 and diacylglycerol (DAG). The IP3 binds to the Type III IP3 receptor (IP3R3), causing release of Ca^{2+} from intracellular stores and subsequent Ca^{2+}-dependent activation of a monovalent cation channel, TRPM5. This causes membrane depolarization, activation of voltage-gated Na^+ channels (VGNaC), and action potentials, which are believed to be required for transmitter release. Knockout of PLCβ2, TRPM5, or α-gustducin compromises responses to bitter, sweet, and umami taste stimuli. The role of the decrease in intracellular cAMP is not known, but it may regulate phosphorylation of downstream signaling effectors or target cyclic nucleotide modulated ion channels.

out Trpm5 varied with the taste field and type of taste quality examined: with bitter compounds, glossopharyngeal nerve responses were greatly diminished while chorda tympani nerve responses were normal; with umami compounds, glossopharyngeal nerve responses were intact while chorda tympani responses were greatly diminished. That target channels in addition to Trpm5 may exist in taste cells comes from the detection of another Ca^{2+}-activated cation conductance in excised taste cell patches from Trpm5 knockout mice (Zhang, Y. *et al.*, 2007). Thus Trpm5 is the primary target channel for the taste cell phosphoinositide signaling pathway: activation of PLCβ2 by Gγ13 would generate IP_3 to activate IP_3RIII, released intracellular Ca^{2+} would activate Trpm5 leading to cation influx and taste cell depolarization. In addition there may be other targets of this pathway as well as other target channels in other pathways.

4.10.2.4 Transduction Elements Specific to Particular Taste Qualities

Although several elements are common to the transduction of bitter, sweet, and umami taste qualities, the only transduction element, aside from the receptors themselves, that is involved in one but not all three taste qualities is α-transducin. As noted above, α-transducin knockouts had a specific effect on umami responses, however, this was only revealed in the α-gustducin knockout background – single knockouts lacking only α-transducin had no effect on bitter sweet or umami (He, W. *et al.*, 2004). That the closely related G protein α-subunits, α-transducin and α-gustducin are not interchangeable in taste signaling comes from studies in which α-transducin was added back as a transgene in α-gustducin knockout mice (He, W. *et al.*, 2002).

That umami transduction might employ unique transduction elements not in common with those of the other GPCR-dependent taste qualities might stem from the multiplicity of receptors and channels implicated in umami. As is further discussed in Chapter Taste Receptors both GPCRs and ion channels have been implicated as umami receptors. Amongst the GPCRs implicated in umami responses are ionotropic glutamate receptors (Lin, W. and Kinnamon, S. C., 1999; Caicedo, A. *et al.*, 2000b), metabotropic glutamate receptors (mGluRs) (Monastyrskaia, K. *et al.*, 1999; Chaudhari, N. *et al.*, 2000), and the heterodimer of T1R1 and T1R3 (Nelson, G. *et al.*, 2001; Li, X. *et al.*, 2002).

4.10.3 Other Transduction Mechanisms

4.10.3.1 Fat Taste

Preference for fatty foods is ubiquitous among mammals. This is not surprising, since lipids represent a significant source of energy and have appealing orosensory qualities (for recent review, see Laugerette, F. *et al.*, 2007). However, whether fat is actually detected as a taste stimulus has been controversial. If fat is detected as a taste stimulus, long chain fatty acids appear to mediate the effect. Rodents prefer long chain fatty acids to either triglycerides or medium-chain fatty acids in preference assays (Fukuwatari, T. *et al.*, 1997) and conditioned taste aversion tests show that rats can specifically detect long chain fatty acids (McCormack, D. N. *et al.*, 2006). Long chain fatty acids are produced from triglycerides by the action of lingual lipase, an enzyme that has been identified in the secretion of von Ebner's glands, which bathe the circumvallate taste buds. In mice, inhibition of this enzyme reduced preference for triglycerides, but not for free fatty acids (Kawai, T. and Fushiki, T., 2003).

4.10.3.1.1 Fatty acid modulation of taste cells

The first evidence for a direct effect of fatty acids was obtained from whole-cell recordings showing fatty acids block delayed rectifier K^+ channels in rat taste cells (Gilbertson, T. A. *et al.*, 1997). These channels are blocked directly by long chain polyunsaturated fatty acids in fungiform taste buds, and by monounsaturated fatty acids in vallate and foliate taste buds. The fatty acid inhibition of K^+ channels depolarizes taste cells and is hypothesized to modulate sensitivity to conventional taste stimuli. In support of this model, low concentrations of linoleic acid augmented preference for subthreshold concentrations of saccharin in two bottle preference tests (Gilbertson, T. A. *et al.*, 2005). Further, licking rates of rats to suprathreshold concentrations of prototypical sweet, salty, sour, and bitter compounds were altered by addition of linoleic and oleic acids to the taste stimuli. Licking rates to sweet stimuli were augmented by the fatty acids, while licking rates to bitter, sour, and salty stimuli were decreased (Pittman, D. W. *et al.*, 2006). Similar psychophysical studies in humans, however, have failed to show a significant effect of fatty acids on either detection thresholds or intensity ratings of

taste stimuli (Mattes, R. D., 2007), suggesting fatty acid modulation of taste may be less important in humans.

4.10.3.1.2 Fatty acid taste receptors

Evidence was obtained recently for a fatty acid transporter that may serve as a specific taste receptor for fat (Fukuwatari, T. *et al.*, 1997; Laugerette, F. *et al.*, 2005). CD36, a lipid-binding protein, is expressed in the apical region of taste cells in both mice and rats. It is highly expressed in circumvallate papillae, but less so in foliate and fungiform papillae. The role of CD36 as a fatty acid transducer is supported by its predicted structure. The protein contains a large extracellular hydrophobic pocket and a C terminal sequence that associates with Src kinases, suggesting a role in intracellular signaling (Laugerette, F. *et al.*, 2005). More definitive evidence for its role in fat sensing came from studies in CD36 knockout mice. These mice lack preference for long chain fatty acids, but have normal preference for other taste stimuli. Further, these mice lack a lipid-induced cephalic phase response normally present in wild-type mice (Laugerette, F. *et al.*, 2005). These data provide the strongest evidence to date that fat may be the sixth primary taste. However, further work is necessary to determine how CD36 activation is converted into a taste signal, which taste cells detect fat, and how fat information is encoded in the nervous system with respect to other taste qualities. Also, it will be important to determine if CD36 is expressed in human taste cells, where it could serve as a substrate to modulate fat intake.

Some evidence also exists for GPCRs for fat. GPR 120 is a fatty acid receptor expressed in enteroendocrine cells of the colon. mRNA for GPR 120 was recently found in circumvallate taste buds, and immunocytochemistry showed intense labeling in the apical region of a subset of rat taste cells (Matsumura, S. *et al.*, 2007). Thus, its expression pattern is consistent with a potential role in fat sensing, but definitive evidence must await knockout of the gene.

4.10.3.2 Water Taste

Although water is not classically considered to have a taste, it is well established that gustatory nerve fibers respond to water applied to the tongue (for review, see Gilbertson, T. A. *et al.*, 2006). The mechanisms involved in the water response are only now beginning to be understood. Gilbertson T. A. (2002) showed that hypo-osmotic solutions lead to an increase in cell capacitance accompanied by activation of a Cl^- conductance. This conductance is similar physiologically and pharmacologically to the well studied swelling-activated Cl^- current observed in other cell types (Jentsch, T. J., 1996). Such a current likely plays a role in regulating taste cell volume in response to varying osmotic taste stimuli. Recently, the water-permeable ion channels involved in the hypo-osmotic swelling were identified (Watson, K. J. *et al.*, 2007). Several aquaporins (AQPs) are expressed in taste cells, including AQP1 and AQP2, which label predominately the basolateral membrane, and AQP5, which labels both apical and basolateral membranes. Whole-cell recording showed that a specific AQP inhibitor significantly reduces hypo-osmotic-induced Cl^- currents in taste cells, suggesting that AQPs are the source of the water influx. Further studies are needed to determine how this leads to the well-characterized water response in afferent nerve fibers.

4.10.4 Signaling to Afferent Nerve Fibers and Adjacent Taste Cells

Taste cells communicate sensory information to afferent nerve fibers as well as to adjacent cells within taste buds (for review, see Herness, S. *et al.*, 2005; Roper, S. D., 2006). Many transmitters have been proposed to contribute to chemical communication in the taste bud, including serotonin, adenosine triphosphate (ATP), glutamate, acetylcholine, norepinephrine, gamma-aminobutyric acid (GABA), and various peptides. Indeed, evidence exists for expression of each of these neuroactive compounds or their receptors in taste buds, but to date only two, ATP and serotonin, have met all the criteria required to be considered as a taste cell transmitter or modulator. By analogy to the nervous system, these criteria include: (1) presence in the presynaptic cell, (2) release upon stimulation, (3) activation of the postsynaptic cell, usually through specific receptors, and (4) mechanism for termination of transmitter action.

4.10.4.1 Adenosine Triphosphate as a Transmitter

ATP is now believed to be the primary transmitter that links taste cells to activation of gustatory afferent

fibers (Finger, T. E. *et al.*, 2005). The first clue that ATP might serve as a taste cell transmitter was the observation that the ionotropic purinergic receptors P2X2 and P2X3 are abundantly expressed on gustatory afferent terminals (Bo, X. *et al.*, 1999). Definitive evidence for a role of P2X2 and P2X3 was obtained from P2X2/P2X3 double knockout mice, which lack behavioral and afferent nerve responses to most taste stimuli (Finger, T. E. *et al.*, 2005). Further, taste stimuli evoke release of ATP from taste cells (Finger, T. E. *et al.*, 2005; Huang, L. *et al.*, 2007; Romanov, R. A. *et al.*, 2007), and the released ATP is likely degraded by NTPDase2, an ecto ATPase abundantly expressed on the membranes of type I (support) taste cells (Bartel, D. L. *et al.*, 2006). Thus, ATP appears to fit all the criteria required to serve as a transmitter in the taste bud. The released ATP also binds to G-protein-coupled P2Y receptors on taste cell membranes (Kataoka, S. *et al.*, 2004; Bystrova, M. F. *et al.*, 2006; Huang, L. *et al.*, 2007), suggesting that ATP may also serve as an autocrine or paracrine modulator in the taste bud. Recent studies using sensitive biosensor cells expressing purinergic receptors have shown that either taste stimuli (Huang, L. *et al.*, 2007) or membrane depolarization (Romanov, R. A. *et al.*, 2007) can evoke ATP release from single type II taste cells, likely via gap junction hemichannels composed of pannexin 1 or connexin 43. Release can be evoked in the absence of Ca^{2+} (Romanov, R. A. *et al.*, 2007), which may explain the curious observation that although type II taste cells generate action potentials, they lack voltage-gated Ca^{2+} channels and conventional synapses with the nervous system (Clapp, T. R. *et al.*, 2004; 2006; DeFazio, R. A. *et al.*, 2006).

4.10.4.2 Serotonin and Other Neuroactive Modulators

Serotonin (5-HT) was originally believed to be the primary taste cell transmitter, since it is widely expressed in taste buds of a variety of species from fish to mammals (Kim, D. J. and Roper, S. D., 1995). In nonmammalian vertebrates serotonin is expressed in Merkel-like basal cells, where it appears to serve as a paracrine modulator in the taste bud (Delay, R. J. *et al.*, 1997). In mammalian taste cells, it is expressed in a subpopulation of type III taste cells (Yee, C. L. *et al.*, 2001). Recent studies show that serotonin is released from single type III cells in response to membrane depolarization and from intact taste buds in response to bitter taste stimuli, presumably in response to ATP released from type II taste cells (Huang, L. *et al.*, 2007). Enzymes for serotonin biosynthesis (DeFazio, R. A. *et al.*, 2006; Ortiz-Alvarado, R. *et al.*, 2006; Seta, Y. *et al.*, 2007) and reuptake (Ren, Y. *et al.*, 1999) are expressed in taste buds, as well as specific serotonin receptors. Both 5-HT_{1A} and 5-HT_3 were amplified by RT-PCR from RNA extracts of taste buds (Kaya, N. *et al.*, 2004). Immunocytochemical labeling showed that 5-HT_{1A} is expressed on the membranes of nonserotonergic taste cells, where it likely mediates the effects of serotonin as a paracrine neuromodulator (Figure 5). 5-HT_{1A} receptor agonists modulate taste cells by inhibiting calcium-activated K^+ currents and voltage-dependent Na^+ currents, suggesting that serotonin affects the membrane excitability of taste cells (Herness, M. S. and Chen, Y., 1997; Herness, S. and Chen, Y., 2000). In contrast, taste cell membranes lack expression of 5-HT_3 receptors, suggesting it may be present on afferent nerve terminals (Kaya,

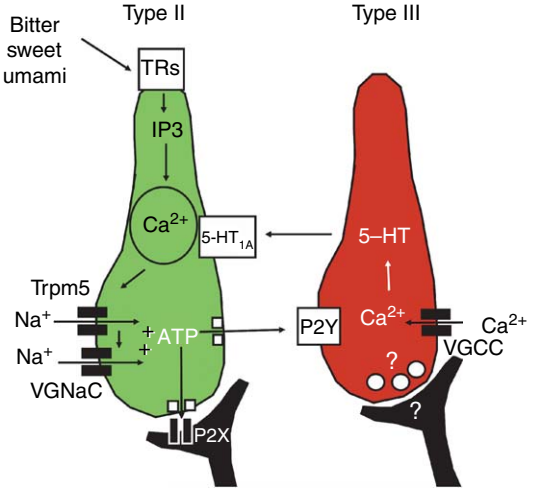

Figure 5 Proposed role of ATP and serotonin in afferent signaling. Bitter, sweet, and umami taste stimuli evoke ATP release from Type II taste cells. The ATP subsequently binds to the ionotropic purinergic receptors P2X2 and P2X3, which are abundantly expressed on afferent nerve fibers. Recent data suggest that the release of ATP is nonvesicular, involving voltage- and Ca^{2+}-gated gap junction hemichannels. ATP also binds to G protein-coupled purinergic receptors (P2Y) on the membranes of Type III taste cells, causing them to release serotonin (5-HT). The 5-HT likely binds to 5-HT_{1A} receptors on Type II taste cells, modulating their sensitivity to sweet and bitter taste stimuli. A major unanswered question is the identity and role of the transmitter at the prominent synapses between Type III taste cells and nerve fibers, but it is not believed to be 5-HT, because 5-HT3 knockout mice have normal behavioral responses to taste stimuli.

N. *et al.*, 2004). However, mice lacking 5-HT_3 receptors have normal behavioral responses to taste stimuli (Finger, T. E. *et al.*, 2005), indicating that serotonin is not likely to be involved in direct activation of afferent fibers. Recent behavioral data suggest a role of serotonin in modulation of taste thresholds in humans. Serotonin reuptake inhibitors, which increase the life time of serotonin in the synaptic cleft, enhance sensitivity to sweet and bitter taste stimuli in healthy adult human subjects (Heath, T. P. *et al.*, 2006). Further studies will be required to determine if 5-HT_{1A} receptors play a role in this modulation.

Norepinephrine (noradrenaline) and its receptors are expressed in subsets of taste cells, suggesting a role in cell-to-cell communication. α- and β-adrenoceptor agonists inhibit outward K^+ currents in taste cells, and multiple α- and β-adrenoceptors are expressed in lingual epithelium (Herness, S. *et al.*, 2002). However, which taste cell types are involved, and whether norepinephrine is an autocrine or paracrine modulator has not been determined. As is the case with serotonin, norepinephrine reuptake inhibitors enhance taste sensitivity in humans, suggesting a role for norepinephrine in modulating human taste thresholds (Heath, T. P. *et al.*, 2006).

Several neuropeptides are expressed in taste buds, including cholecystokinin (CCK), vasoactive intestinal peptide (VIP), and neuropeptide Y (NPY; Shen, T. *et al.*, 2005; Zhao, F. L. *et al.*, 2005). These peptides are all members of the brain-gastrointestinal tract family of peptides, which modulate feeding circuits in the brain. Thus, it is of interest that they are also expressed in taste receptor cells, the gateway to food intake. All three peptides are largely coexpressed with gustducin in circumvallate taste buds, suggesting that they are expressed primarily in bitter sensitive taste cells. Interestingly, NPY and CCK both modulate an inwardly rectifying K^+ current in taste cells, but in opposite directions – NPY enhances the current to hyperpolarize taste cells, while CCK inhibits it, resulting in taste cell depolarization.

4.10.4.3 Other Candidate Transmitters

While it is clear that ATP released from type II cells activates purinergic receptors on gustatory nerve fibers, the identity of the transmitter at the prominent synapse between type III taste cells and nerve fibers remains enigmatic. Investigators have failed to detect ATP release from type III taste cells (Huang, L. *et al.*, 2007; Romanov, R. A. *et al.*, 2007), and serotonin is unlikely to directly activate nerve fibers, as discussed above. These synapses are normally associated with clusters of clear vesicles (see Chapter Ultrastructure of Taste Buds), suggesting they may contain a conventional transmitter. Glutamate has long been proposed as a transmitter in taste buds, due to the expression of the glial glutamate transporter GLAST in type I taste cells (Lawton, D. M. *et al.*, 2000), and the expression of ionotropic glutamate receptors on the basolateral membranes of taste cells (Caicedo, A. *et al.*, 2000a). Another conventional transmitter candidate is acetylcholine, which modulates taste cells via muscarinic receptors (Ogura, T., 2002; Ogura, T. and Lin, W., 2005). However, the source of acetylcholine is still unclear. Recently, GAD67, involved in the synthesis of GABA, was shown to be expressed exclusively in type III cells (DeFazio, R. A. *et al.*, 2006), suggesting GABA may play a role at this synapse. Further studies are necessary to determine if type III taste cells release any of these potential transmitter candidates.

Glossary

alar plate A sensory region located dorsally in the embryonic spinal cord and hindbrain.

barbels Whisker-like, taste bud-bearing organs located near the mouth in some fishes, for example catfish.

basal plate A motor region located ventrally in the embryonic spinal cord and hindbrain.

bauplan Building plan: In taxonomy, the common properties of the members of a systematic group of animals.

brachium conjunctivum A white matter landmark in the pons consisting of axon bundles exiting the cerebellum.

Golgi stain A specialized stain showing cell bodies, dendrites and axons of a small, random subset of neurons in a histological section.

lemniscal pathway A sensory pathway that ascends from the spinal cord or brainstem, through the thalamus, to the cerebral cortex, that is from first-order to second-order to third-order nuclei, etc.

limbic Brain regions and functions concerned with visceral processes, e.g., the emotional or homeostatic status of the organism.

Nissl stain A routine stain showing all neuronal cell bodies in a histological section.

nucleus ambiguus A group of motor neurons that innervate pharyngeal muscles.

parabrachial nucleus A group of neurons surrounding the brachium conjunctivum in the dorsal pons.
primary sensory nucleus A brain region first activated by peripheral inputs; the neuronal group in the medulla receiving direct connections from peripheral nerves.
second-order sensory nucleus A brain region, located rostral to the medulla, that receives input from a primary sensory nucleus.
somatotopic A spatial representation that maps the sensory surface of an organism within the nervous system.
telencephalic Related to the forebrain.
teleost A group of bony, ray-finned, fishes with movable upper jaws.
third-order sensory nucleus A brain region that receives input from a second-order nucleus.

4.11.1 Introduction and Overview

The sense of taste in all complex animals begins with specialized chemoreceptors located in and around the mouthparts. These receptor organs are crucial in determining the palatability of potential food items and in orchestrating the appropriate ingestive or avoidance reactions. The organization of the neural centers activated by the receptors is the topic of this chapter, which presents a comparative perspective. Comparison of invertebrate and vertebrate systems may be instructive in terms of recognizing general principles of processing or organization, but data from one group is not likely to be directly applicable to the other group. For example, taste receptor organs in invertebrates involve sensory neurons with axons directly extending into the central nervous system. In the vertebrates, taste receptor organs (taste buds) consist of modified epithelial cells, not neurons. The taste bud cells connect with the primary taste neurons which lie in remote cranial ganglia, and it is the central processes of these ganglion cells that convey the taste message into the central nervous system. Thus, the taste system in invertebrates, for example, leech, fruit fly, is analogous, but not homologous to the taste system in vertebrates although commonalities do exist, probably through convergence (Finger, T. E., 2006). In contrast, the taste system in the different vertebrates is homologous (derived from a common ancestral condition), and so similarities in organization and mechanism are likely. Many such homologies are apparent when comparing the taste systems of different groups within vertebrates.

The general structure and organization of the taste system in vertebrates suggest that this system evolved in the earliest vertebrates and therefore is part of the common bauplan of all vertebrates. Taste buds are present in all vertebrates including lampreys, elasmobranches, bony fishes, amphibia, and amniotes including mammals. Comparison of the organization of the taste systems in various vertebrates contributes to an understanding of which features are part of the common organizational plan and which features may be derived for particular species or groups. This chapter first describes the general organizational plan for the central representation of taste within the brains of vertebrates. Then it examines in more detail the neuroanatomical organization of the taste system in two well-studied vertebrate groups: teleost fish and mammals, especially rodents.

4.11.1.1 Functional Organization of the Taste System in Vertebrates

Taste buds serve as sentinels for the digestive tract. They are positioned to allow the animal to assess the chemical composition of potential food items before they are given entrance to the alimentary canal. Not surprisingly then, stimulation of taste buds can evoke either ingestive or rejection reflexes. Yet taste does more than to merely serve as a go/no-go switch for foods. The sense of taste offers a conscious awareness of the composition of foods and is used to preferentially ingest particular substances according to past experience. Concomitant with a role in feeding, the sense of taste is involved in triggering digestive reflexes appropriate to the items ingested.

The roles for the gustatory system can be divided into three broad functional domains: (1) local brainstem pathways – reflexive action involving oropharyngeal muscles and digestive processes, (2) lemniscal pathways – mediating conscious awareness of what is being eaten, and (3) basal forebrain (limbic) pathways – visceral functions relating to hunger

status, homeostasis, and drive state. Accordingly, it is not surprising that taste inputs to the brain ultimately influence centers associated with each of these functions, respectively: (1) oromotor and visceromotor nuclei of the brainstem, (2) a lemniscal system conveying information to specific gustatory areas of the forebrain, for example, gustatory cortex, and (3) basal forebrain regions, for example, the hypothalamus and amygdala, areas that are interconnected with the gustatory brainstem and typically associated with drive states, emotions, and homeostasis.

4.11.1.1.1 Primary sensory nuclei

In all vertebrates, taste information is conveyed to the central nervous system via three cranial nerves: the facial (CN VII), glossopharyngeal (CN IX), and vagus (CN X) nerves. The taste fibers in these nerves project to a restricted portion of the visceral sensory column of the medulla, an area situated dorsolateral to the sulcus limitans, a groove in the lateral wall of the ventricle. In the embryo, this sulcus separates alar plate from basal plate, and therefore separates sensory nuclei dorsally, from motor nuclei ventrally. In the medulla, the embryonic neural tube spreads apart dorsally to form the fourth ventricle so that the alar plate comes to lie dorsolateral of the basal plate. The visceral sensory column lies along the medioventral margin of the alar plate, where it is adjacent to the basal plate (Figure 1).

The viscerosensory column (Herrick, C. J., 1922) is, however, not a single homogeneous structure any

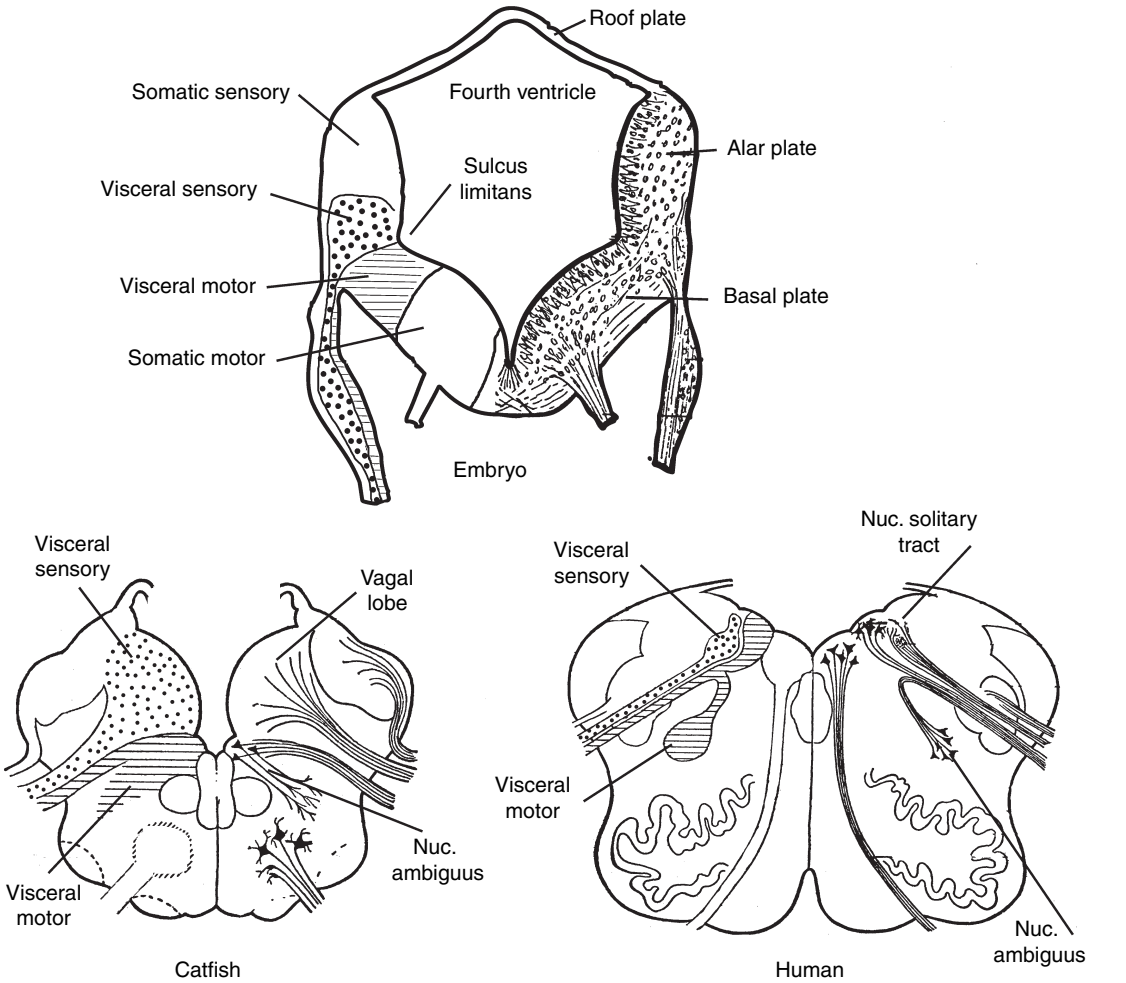

Figure 1 Semischematic diagrams showing the situation of the visceral sensory and motor columns in cross sections of the medulla in the embryo (above), the adult catfish (lower left) and adult human (lower right). In all situations, the visceral sensory column lies immediately dorsal to the sulcus limitans, while the visceral motor column lies immediately ventral. This same relationship holds in the adult brain of all vertebrate species. Adapted from Herrick, C. J. 1922. An Introduction to Neurology. W.B. Saunders Co.

more than the dorsolaterally adjacent somatic sensory column is a unitary structure. The somatic sensory column, for example, contains special somatic components: cochlear nuclei and vestibular nuclei, as well as general somatic components, i.e., trigeminal nuclei. Similarly, the visceral sensory column contains special visceral components for taste, and general visceral components for interoceptive functions carried on the vagus nerve including those mediated by digestive, cardiac, and respiratory afferent fibers. The taste portion of the visceral sensory column lies rostral and lateral to the general visceral components. In amniote vertebrates, the visceral sensory column is represented by the nucleus of the solitary tract (NST), containing separable gustatory and general visceral subdivisions. In fishes, the visceral sensory column is grossly divisible into lobes or lobules which protrude dorsally into the fourth ventricle. These lobules form clear anatomical boundaries between the gustatory and general visceral components of the nuclear complex. The gustatory lobes in the medulla in fishes are homologous to the gustatory portion of the NST in other vertebrates.

The gustatory and general visceral portions of the visceral sensory complex differ not only in terms of inputs but also in terms of connectivity with the rest of the brain. The general visceral components of the visceral complex maintain intimate reflex interconnections with the subjacent dorsal motor nucleus of the vagus, a preganglionic parasympathetic nucleus (Rogers, R. C. and McCann, M. J., 1993) and areas of the reticular formation that influence autonomic outflow (Ross, C. A. *et al.*, 1985). In addition, the general visceral subnuclei are extensively interconnected with limbic structures such as hypothalamus and amygdala (Ricardo, J. A. and Koh, E. T., 1978). The gustatory nuclei not only have interconnections with these limbic areas but possess unique connections as well. The reflex connections of the gustatory subnuclei involve oromotor centers and salivatory nuclei much more so than they do the dorsal motor nucleus of the vagus (Cunningham, E. T. and Sawchenko, P. E., 2000). In addition, the gustatory nuclei give rise to a unique lemniscal system conveying gustatory information to the thalamus and thence to a primary gustatory region of the cerebrum (e.g., gustatory cortex in mammals).

4.11.1.1.2 Local reflex pathway

Activation of the gustatory system will result in oropharyngeal movements (whether they be ingestion and swallowing or gagging and rejection) as well as reflex salivation and activation of the GI tract. The gustatory nuclei have reflex connections ending on oromotor nuclei (trigeminal motor nuc., nuc. ambiguus, hypoglossal nuc.) and in the adjacent premotor reticular formation. The more rostral gustatory nuclei tend to have more connections with reticular formation and anterior oromotor centers, while more caudal gustatory nuclei have more substantial connections with oropharyngeal motoneurons of the nucleus ambiguus. Homologous reflex pathways in fish and mammals will be described.

4.11.1.1.3 The gustatory lemniscus

Like other special senses, the gustatory system maintains a chain of connections within the brain with an ultimate target in the telencephalon. A labeled-line sensory pathway that ascends from the medulla to the thalamus and finally to cerebral cortex is known as a lemniscus. In mammals, the ultimate target of the gustatory lemniscus is primary gustatory cortex. In nonmammalian vertebrates, the telencephalic target is a restricted area within the dorsal telencephalon.

The gustatory lemniscus starts from the primary gustatory nuclei of the medulla to reach a specific thalamic relay nucleus. The ascending fibers proceed along two routes. Some percentage of the fibers more in some species (e.g., monkey) fewer in others (e.g., rat) ascend through the brainstem directly to reach the ipsilateral taste nucleus of the thalamus. Other fibers from the primary sensory nuclei ascend only as far as the ipsilateral secondary viscerosensory nucleus of the dorsal pons (i.e., pontine taste area (Norgren, R. and Leonard, C. M., 1973), parabrachial nuc. (Norgren, R. and Pfaffmann, C., 1975), in mammals, superior secondary gustatory nuc. (Herrick, C. J., 1905) in fish. The secondary viscerosensory nucleus of the pons, like the primary viscerosensory column of the medulla, contains distinct gustatory and general visceral components. The gustatory component of the secondary viscerosensory nucleus projects to the ipsilateral thalamic taste nucleus that is targeted by the direct ascending gustatory lemniscal system. The thalamic gustatory nucleus relays taste information to the telencephalic gustatory target which, in mammals, is gustatory cortex.

4.11.1.2 Visceral–Limbic Connections

The gustatory system, consistent with its visceral sensory nature, has extensive interconnection with the portions of the limbic system involved in

regulation of homeostatic functions and drive states. The gustatory modality is crucial in the selection of particular foods. The choice of preferred foods changes according to an animal's physiological state (specific appetites, e.g., sodium appetite) and past experience. For example, a sodium-deprived rat will specifically seek out sodium salts in preference to other salts. Similarly, an animal that has fallen ill after ingesting a novel food will develop a strong aversion to the taste associated with that food (conditioned taste aversion). Both the specific appetites and conditioned taste aversions require coordination of limbic areas (hypothalamus and amygdala) with incoming gustatory information. Hence it is not surprising to find that ascending gustatory information reaches these limbic areas as well as the thalamocortical system.

4.11.1.3 The Gustatory Sense as a Visceral Modality

The gustatory sense has a unique location at the boundary between the external environment and the internal milieu. In some vertebrates (and even young children!), the gustatory system is used as an exteroceptive sense to gather information about the external world. But in all vertebrates, the gustatory modality is used to monitor intake of substances into the alimentary tract and to protect the airways from foreign substances, for example, laryngal taste buds which line the airway side of the larynx detect food or liquid that might be inhaled (Dickman, J. D. and Smith, D. V., 1988). The farther posterior a taste bud lies in the oropharynx, the more it serves as a visceral sensory organ; the more anterior a taste bud lies (e.g., tip of the tongue; barbels and lips of fishes), the more it is used as an exteroceptive special sense.

The most posterior taste buds are innervated by the vagus nerve, a mixed nerve containing some fibers which convey taste from these buds, while other fibers convey multiple general visceral modalities from interoceptive chemoreceptive end organs. These general visceral modalities, for example, information on blood gases, cardiac functions, upper GI tract functions, project into caudal portions of the brainstem viscerosensory complex (nuc. solitary tract). These inputs are relayed to brainstem visceromotor centers, to the pontine viscerosensory relay (parabrachial complex), and to the limbic areas of the forebrain including hypothalamus and amygdala. These limbic connections are highly reminiscent of the limbic relays for taste information, which they parallel to a large extent; their organization reflects the visceral nature of the gustatory system.

4.11.2 Gustatory Centers in Fish: A Comparative Viewpoint

This section will describe how taste information is represented in the brains of nonmammalian vertebrates and especially teleost (bony) fishes. Understanding the organization of the gustatory system across vertebrates is important in two ways. First, it allows us to abstract general organizational principles that are evolutionarily conserved and which are likely to underlie the central organization of taste systems in mammals including humans. Second, the gustatory system is comparatively large in many fishes, and so the central taste nuclei represent a much larger portion of the brain, thus making the system more amenable to study. The basic connectivity of the brain is preserved through evolution, so understanding these pathways in fish will shed light on the basic organization of these systems in mammals.

What are the major features of the central gustatory system that can be discerned in these comparative studies? First, the primary principle of organization of the primary visceral nuclei, including the taste nuclei, is a somatotopic, or organotopic, representation. In the taste nuclei of fishes, a fine-grained topography is a recurrent theme across species, with particular sensory appendages or specializations being represented in elaborate corresponding central structures. This detailed somatotopic arrangement is mirrored in the primary general visceral nuclei in both fish and amniote vertebrates (Katz, D. M. and Karten, H. J., 1983; Altschuler, S. M. *et al.*, 1989) where different organs of the digestive and respiratory systems target specific subnuclei of the primary visceral sensory complex. Second, reflex systems arising from the different parts of the gustatory nuclear complex are different according to the end organ or part of the oral cavity innervated. Accordingly, facial taste information, which arises from more distal sensory fields, has connectivity more related to movements of the body, head, or tongue, whereas vagal taste information, arising from the posterior part of the oral cavity, has connectivity with motor systems driving swallowing. Third, despite the elaborate detail of the primary gustatory nuclei, the second-order nuclei do not mirror this somatotopic encoding of the information. The implication is

that either the somatotopic information is encoded in some other fashion as it is relayed to higher centers or else the somatotopic information is utilized for processing in the primary sensory nuclei but is less important higher in the neuraxis. Nonetheless, despite the loss of the fine-grain somatotopy (Marui, T., 1981), the secondary nucleus does maintain the gross separation of facial and vagal gustatory information (Morita, Y. *et al.*, 1980) as well as gustatory and general visceral functions (Finger, T. E. and Kanwal, J. S., 1992).

4.11.2.1 Primary Gustatory Nuclei

A great deal of diversity exists in terms of the relative size and complexity of the taste system in the 20 000 species of teleost fishes. Some, for example, zebrafish, have a relatively undistinguished gustatory system encompassing both intraoral and external taste buds. Other fishes, including catfishes (order: siluriformes), many carps (family: cyprinidae) including goldfish, goatfish (family: Mullidae), and *Heterotis*, an unusual African fish unrelated to the mainstream teleosts, have elaborate taste bud arrays and central specializations. Because of the diverse species exhibiting such gustatory specializations, the elaboration of the system must have occurred independently several times during evolution. Despite these independent enlargements of the system in some species, numerous similarities still exist, and these must point to the underlying organizational scheme that formed early in vertebrate evolution. Such traits are likely to be consistent throughout all groups from fishes to amniote vertebrates including humans.

In all vertebrates, taste inputs arrive on three cranial nerves: CN VII (facial), CN IX (glossopharyngeal), and CN X (vagus). The facial nerve innervates taste buds situated farthest from the esophagus. In mammals, these are on the tip of the tongue, but in most fishes, taste buds occur on the external epithelium as well as in the oral cavity. Those taste buds lying outside of the oral cavity are always innervated by branches of the facial nerve. In fishes with specialized taste appendages (barbels), for example, catfish (Atema, J., 1971) and goatfish (Kiyohara, S. *et al.*, 2002), there is a concomitant relative enlargement of the facial taste system. Conversely, other fish species exhibit a relative enlargement and specialization of the vagal taste system which innervates elaborations of palatal or branchial taste organs (Braford, M. R. J., 1986; Finger, T. E., 1988).

As in other vertebrates, the three taste nerves enter the medulla to terminate in the viscerosensory column of nuclei extending along the wall of the fourth ventricle from near the obex to the level of the pontomedullary junction. The facial nerve terminates most rostrally in this column while the vagus nerve ends most caudally; the glossopharyngeal zone occupies an intermediate position. Even in fishes lacking an elaborately derived gustatory system, this overall organization is obvious. The three taste nerves terminate in serial order: facial terminals most anterior, glossopharyngeal terminals in the middle, and vagal taste inputs most posterior of the three. In all fishes, the general visceral components of the vagus nerve (e.g., innervating gut) terminate still more posteriorly in the viscerosensory column (Morita, Y. and Finger, T. E., 1985b; 1987).

Because the facial nerve taste system and the vagal nerve taste system innervate different populations of taste buds and terminate in clearly different lobes of the medulla, straightforward lesion experiments have been feasible to determine functional and behavioral differences between these systems. Atema J. (1971) ablated either the facial or vagal lobe in catfish to show that the facial taste system is involved in food localization, while the vagal taste system is necessary for ingestion and swallowing. The reflex connections arising from each of the gustatory lobes are commensurate with the behaviors and movements driven by each of these subsystems. The facial lobe is connected to premotor reticular formation that is involved in orientation to external food sources (Finger, T. E. and Morita, Y., 1985; Morita, Y. and Finger, T. E., 1985a); the vagal lobe has a tight reflex connection to the nuc. ambiguus motoneurons necessary for swallowing of identified food items.

4.11.2.1.1 Facial nerve specializations

The peripheral gustatory organs are especially numerous in those species with elaborate external gustatory appendages used to find food in the environment. Such species include catfishes, goatfishes, and gadids (cods and their relatives). These species are not closely related, emphasizing that gustatory specializations have evolved numerous times during fish phylogeny. Nonetheless, in each of these forms, the elaboration of the external, facially innervated taste periphery results in elaboration of the rostral part of the gustatory sensory column. In fish with an elaborate gustatory periphery, the rostral part of the viscerosensory column bulges medially and dorsally into the fourth ventricle to form an obvious facial lobe (Figure 2).

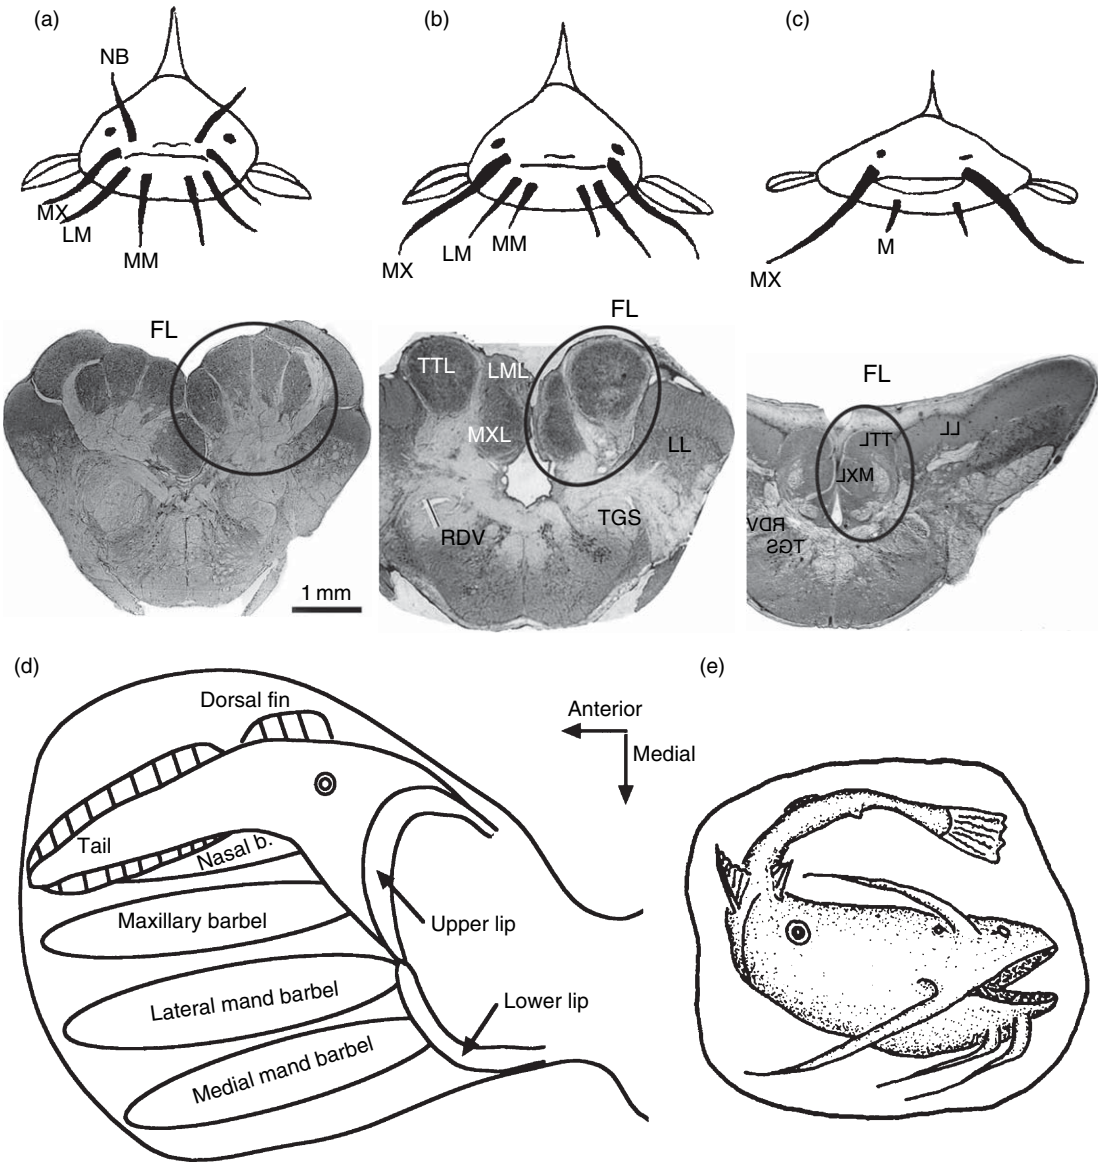

Figure 2 (a–c) The relationship between the number of barbels and the number of lobules in the facial lobe can be appreciated in these matched front views of the fish and cross sections of the rostral medulla in three different species of catfishes. (a) *Plotosus lineatus* has four barbels on each side and four lobules to the facial lobe. (b) *Arius felis* has three barbels and three lobules. (c) *Silurus asotus* has only two barbels and two lobules. (d, e) Semischematic diagrams of the piscunculus in the facial lobes of two species of catfish. A piscunculus is a distorted map of the receptor surface in the brain similar to the somatosensory homunculus drawn for the representation of touch in human somatosensory cortex. (d) The detailed somatotopic organization of the facial lobe of *Plotosus lineatus* can be seen in this figure. The seemingly disproportionate size of the barbels is related to the high density of taste buds on these organs. Representation in the facial lobe is in proportion to amount of taste input and not physical size of the receptor organ. (e) A more fanciful piscunculus projected onto the facial lobe of the bullhead catfish, *Ictalurus nebulosus*. (a, c) Parts of this figure were reprinted from Kiyohara, S. and Caprio, J. 1996. Somatotopic organization of the facial lobe of the sea catfish *Arius felis* studied by transganglionic transport of horseradish peroxidase. J. Comp. Neurol. 368, 121–135, with permission of Wiley Press. (d) Reprinted with permission from Kiyohara, S. and Tsukahara, J. 2005. Barber Taste System in Catfish and Goatfish. In: Fish chemosenser (*eds.* K. Reutter and B. G. Kapoor), pp. 175–211. Science Publishers. (e) Reprinted with permission from Wiley Press from Finger, T. E. 1978. Gustatory pathways in the bullhead catfish. II. Facial lobe connections. J. Comp. Neurol. 180, 691–705.

The structure and complexity of the facial lobe in each species match well the peripheral elaborations present on the animal. In catfishes, the number of lobules present exactly corresponds to the number of peripheral barbels the fish has (Kiyohara, S. and Caprio, J., 1996). In goatfish, the elongate single barbel is represented in a recurved tubular neuropil that maintains a precise somatotopic map of the peripheral end organ (Kiyohara, S. *et al.*, 2002). In codfish, with a simple single barblet, the facial lobe is present but is not particularly elaborate.

4.11.2.1.2 Vagus nerve specializations

Some fishes have an elaborate intra-oral food-sorting apparatus innervated by the vagus nerve. In carps, this mechanism involves the gill arches and palate (Sibbing, F. A. *et al.*, 1986; Osse, J. W. *et al.*, 1997). In the unrelated Osteoglossmorph, *Heterotis,* the food sorting is accomplished in a specialization of the gill chamber (Braford, M. R. J., 1986). In both cases, the vagal taste information enters an elaborate, laminated vagal lobe. In goldfish (and probably *Heterotis*), the taste periphery is represented in a fine-grain orototopic fashion, matching the structure of the peripheral end organ: spiraled in *Heterotis*, a hemisphere in goldfish (Morita, Y. and Finger, T. E., 1985b) (Figure 3).

4.11.2.2 Brainstem Reflex Connections

The gustatory lobes in fishes give rise to local connections to adjacent nuclei and reticular formation

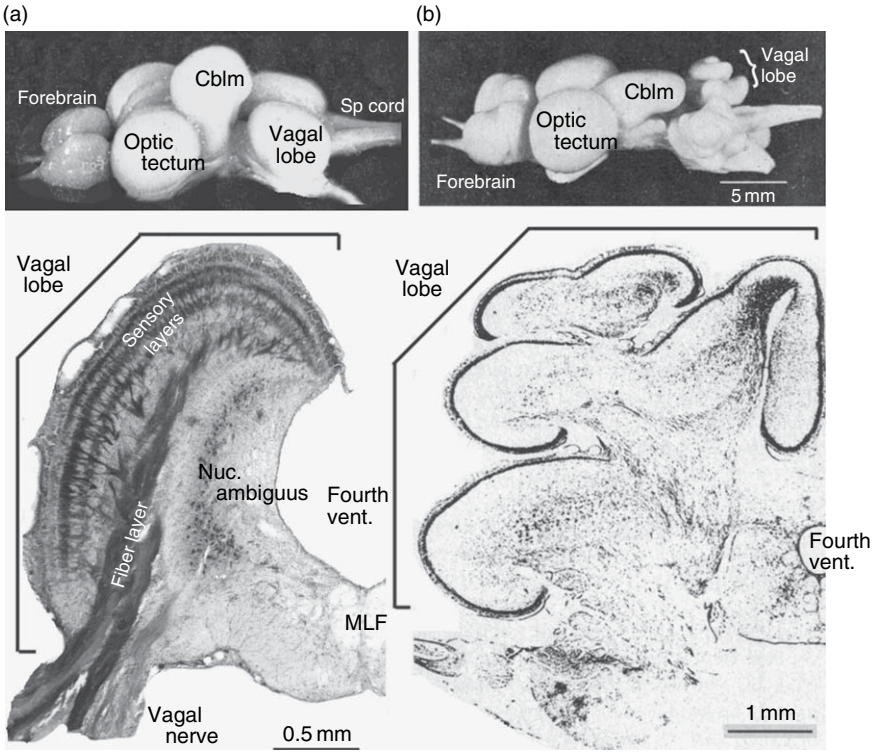

Figure 3 In some fish species, the vagal lobe, which is homologous to the vagal portion of the NST, is quite elaborate and may constitute nearly 20% of the entire brain mass. (a) In the common goldfish, *Carassius auratus*, the vagal lobe is a large, laminated hemisphere protruding from the dorsolateral surface of the medulla. Above: Lateral view of the brain. The large size of the vagal lobe can be appreciated in relation to the rest of the brain. Below: Cross section of the medulla through the vagal lobe, showing the left half of the brain (medial to the right). The laminated nature of the vagal lobe in goldfish is readily apparent in this preparation in which the vagus nerve was filled with the tracer horseradish peroxidase (HRP). The sensory layers lie along the outer half of the lobe overlying the fiber layer. The sensory layers are homologous to the vagal taste part of the NST. The motoneurons that innervate the palate, part of the nuc. ambiguus (visceral motor column) lie deeper in the lobe and are retrogradely labeled by HRP in this preparation. (b) In the African fish, *Heterotis niloticus*, the vagal lobe assumes a spiral shape matching a spiraled food-sorting organ of the branchial cavity (Braford, M. R. J., 1986). Above: The vagal lobe corkscrews dorsolaterally outward from the medulla. Below: Cross section of the medulla through the vagal lobe showing the left side of the brain. Three turns of the spiral can be seen in section. The superficial layer of small closely packed cells is similar to the superficial layer of the vagal lobe in goldfish (left).

areas of the medulla as well as ascending and descending connections (Herrick, C. J., 1905; Finger, T. E., 1978; Finger, T. E. and Morita, Y., 1985). The distinct nature of these reflex connections is more evident in these fishes than it is in mammals, but the same principle obtains. Reflex connections from each division of the visceral sensory column are appropriate for the particular organ or system represented (Figure 4). Thus, for example, general visceral sensory nuclei (GVM) have reflex connections with the general visceral motor nuclei (DMNX) that drive the autonomic nervous system (Altschuler, S. M. *et al*, 1989; Goehler, L. E. and Finger, T. E., 1992; Rogers, R. C. and McCann, M. J., 1993). Within the brainstem gustatory complex itself, distinct reflex channels are evident according to the particular peripheral organ innervated. Thus the subnucleus representing the pharynx (GVL) maintains reflex connections with the motoneurons that drive the pharyngeal musculature (nAphar). Similarly, the areas representing the palate (VLs) have reflex connections with motoneurons driving the palate (nApal – the motor layer of the vagal lobe). Finally, the areas representing taste buds on the lips and external body surface are connected to the subjacent reticular formation which provides coordinated output to the motor nuclei necessary to drive movements of the body and head (Kanwal, J. S. and Finger, T. E., 1997).

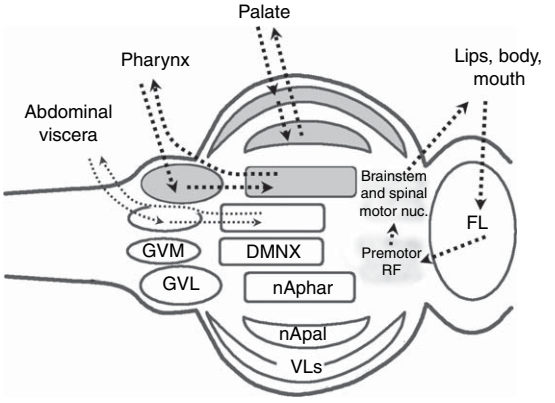

Figure 4 Schematic diagram of a dorsal view of the medulla of a goldfish, anterior to the right. The different reflex systems for the four visceral subsystems are illustrated. The abdominal viscera are innervated by the general visceral branch of the vagus nerve which projects centrally to the medial division of the general visceral nucleus (GVM) and commissural nucleus of Cajal. As in mammals, these maintain an intimate reflex system with the dorsal motor nucleus of the vagus (DMNX). Three semi-independent taste reflex systems also can be identified (shaded in gray): (1) pharyngeal, (2) palatal and caudal oral cavity, and (3) taste buds on the lips and external body surface. Each is connected to a different motor subsystem. The pharyngeal sensory nucleus (GVL) has reflex connections to the pharyngeal motor pool (nAphar). The sensory layers of the vagal lobe (VLs) have a topographically organized reflex connection with the pool of nuc. ambiguus neurons that extend into the vagal lobe motor layer (nApal). The facial lobe gustatory system, which drives complex movements of the body and head for orientation to external food sources, has connections to the premotor reticular formation. DMNX, dorsal motor nucleus of the vagus; FL, facial lobe; GVL, general visceral nucleus, lateral component; GVM, general visceral nucleus medial component; nApal, palatal portion of the nucleus ambiguus (=motor layers of the vagal lobe); nAphar, pharyngeal portion of nucleus ambiguus; VLs, sensory layers of the vagal lobe. Adapted from Goehler L. E. and Finger T. E. (1992) and Kanwal J. S. and Finger T. E. (1997).

4.11.2.3 Second-Order Gustatory Nuclei

The principal target for the ascending secondary gustatory fiber systems is the superior secondary gustatory nucleus (Herrick, C. J., 1905) which is homologous to the pontine taste area or parabrachial nuclear complex in mammals (Norgren, R. and Leonard, C. M., 1973; Norgren, R. and Pfaffmann, C., 1975). In fishes, as in mammals, the superior secondary gustatory nucleus lies in the dorsal pons adjacent to the superior cerebellar peduncle, or brachium conjunctivum. Whereas in mammals, the gustatory portion of the parabrachial complex is a small, poorly differentiated region; in fishes with large gustatory systems, the superior secondary gustatory nucleus is a large well-differentiated nucleus clearly divided into three or more compartments (Finger, T. E., 1978; Morita, Y. *et al*., 1980; Finger, T. E. and Kanwal, J. S., 1992). The facial lobe (taste) projects to the most medial subnucleus; the vagal lobe (taste) projects laterally, and the commissural nucleus of Cajal and associated general visceral nuclei project to a superior secondary general visceral nucleus, ventral and anterior of the secondary gustatory nuclei (Morita, Y. *et al*., 1980; Finger, T. E. and Kanwal, J. S., 1992; Yoshimoto, M. *et al*., 1998). The secondary gustatory and general visceral nuclei exhibit distinct histochemical differences as well as the differences in connectivity (Finger, T. E. and Kanwal, J. S., 1992). A substantial bilateral projection exists so that the superior secondary gustatory nucleus receives information from both sides of the body and mouth (Figure 5).

Although the superior secondary gustatory nucleus in fishes is often very large and well differentiated, the fine topography so evident in the primary gustatory centers appears largely lost in the

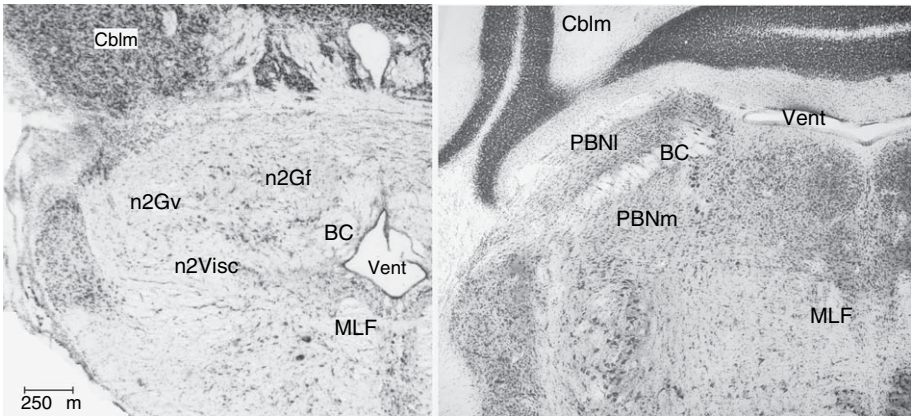

Figure 5 The secondary gustatory nuclei of the pons in (left) a catfish (*Ictalurus punctatus*) and (right) a mouse shown at the same magnification. In fishes, this nucleus is the superior secondary gustatory nucleus (n2G) whereas in mammals, it is called the parabrachial nucleus (PBN) or pontine taste area. In these species, as in all other vertebrates, the secondary gustatory nuclei lie adjacent or surrounding the Brachium conjunctivum (BC) which carries the ascending output from the cerebellum. In fishes, the n2G is divisible into a general visceral zone (n2visc) and a gustatory zone, itself divisible into a facial taste relay (n2Gf) and a vagal taste relay (n2Gv). The parabrachial complex also contains several subdivisions, the most prominent being a lateral subnucleus (PBNl) dorsolateral to the BC and a medial subnucleus (PBNm) ventral to the BC. BC, brachium conjunctivum; Cblm, cerebellum; MLF, medial longitudinal fasciculus; vent, ventricle (rostral end of fourth ventricle).

second-order nucleus. Receptive fields are large rather than discrete (Marui, T., 1981; Lamb, C. F. and Caprio, J., 1992), and small injections of tracer into the primary gustatory nuclei label widespread terminals throughout large areas of the secondary gustatory complex.

4.11.2.4 Ascending Fiber System

As mentioned above, ascending gustatory information targets two different sorts of nuclei in the forebrain. The first is a specific taste lemniscal pathway with an ultimate telencephalic target. The second is a more diffuse ascending system targeting a variety of limbic structures including the hypothalamus and amygdala.

In mammals, the telencephalic target of the gustatory lemniscus is gustatory cortex; the thalamic relay is VPMpc (parvocellular subnucleus of the ventroposteriomedial nucleus of the thalamus). Forebrain organization in fish is still being debated, but the clearest formulation names the third-order thalamic gustatory target as the preglomerular tertiary gustatory nucleus (Wullimann, M. F., 1988; Rink, E. and Wullimann, M. F., 1998; Yoshimoto, M. *et al.*, 1998). This tertiary gustatory nucleus relays taste information to a caudal, medial portion of the dorsal forebrain (dDm) (Kanwal, J. S. *et al.*, 1988; Yoshimoto, M. *et al.*, 1998). Based on connectivity and physiology, the gustatory part of dDm appears homologous to gustatory cortex.

The secondary gustatory nucleus also gives rise to a more diffuse ascending fiber system. In mammals, the system extends from the parabrachial nucleus (PBN) and terminates in various limbic structures including hypothalamus and amygdala (Nomura, S. *et al.*, 1979; Halsell, C. B., 1992). Likewise in fishes, the superior secondary gustatory nucleus projects broadly to limbic forebrain areas including the hypothalamus and probable amygdalar equivalent zones (Lamb, C. F. and Finger, T. E., 1996; Yoshimoto, M. *et al.*, 1998; Folgueira, M. *et al.*, 2003).

4.11.3 Gustatory Pathways in Mammals

This section describes the taste and general viscerosensory systems in mammals and highlights the many features of the organization of these systems in mammals which are comparable to those described for fish in the last section.

4.11.3.1 Primary Sensory Nucleus

The central sensory nucleus that receives taste input from the periphery, in mammals, is the NST. The nucleus is an extensive viscerosensory cell grouping that is small in the dorsoventral and mediolateral

planes, but long rostrocaudally. In fact, the NST extends throughout nearly the entire length of the medulla, from the level of the cochlear nucleus rostrally, where it is positioned somewhat laterally beneath the vestibular nuclei, to the spinal-medullary junction caudally, where it is positioned on the midline below the area postrema. The NST has, embedded laterally within it, the histologically distinct, rostrocaudally running solitary tract, the structure that gives the nucleus its name.

4.11.3.1.1 Primary afferent inputs

The solitary tract contains all the axons of the cranial nerves that provide input to the NST from the periphery. Thus, afferent axons from cranial nerves VII, IX, and X all travel in the tract and give off terminal branches that synapse in the NST. These inputs, which include both taste (special viscerosensory) and general viscerosensory axons (e.g., from the gastrointestinal organs), are arranged topographically in the nucleus (Figure 6). This topography is primarily

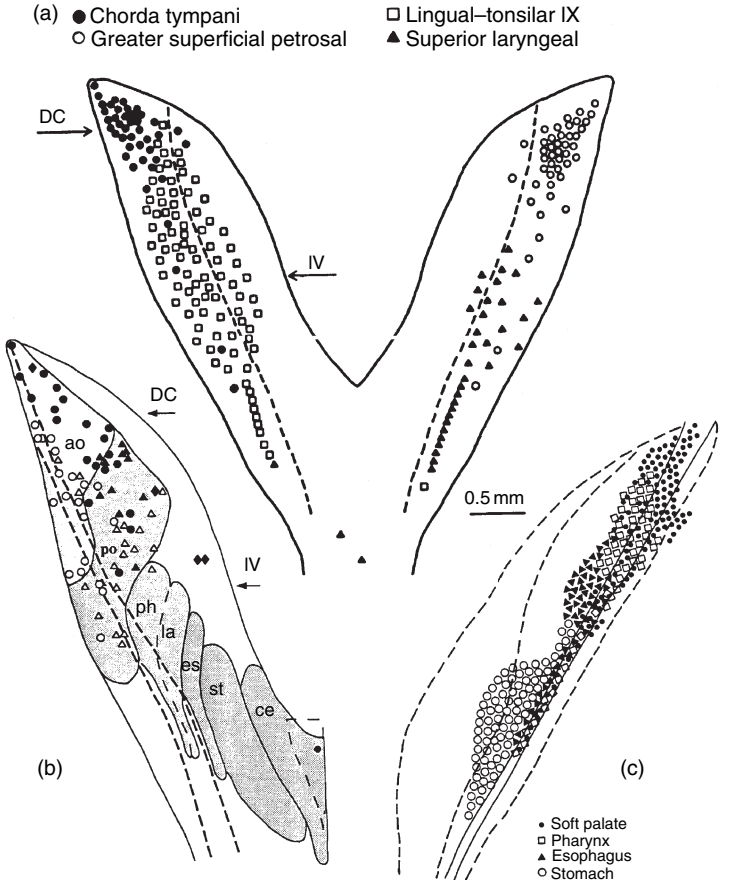

Figure 6 Horizontal depiction of the entire nucleus of the solitary tract in rat showing the topography of primary afferent inputs and of responses to oral and alimentary tract stimulation. Rostral is at the top of the figures. (a) Distribution of terminals of the peripheral gustatory nerves. Chorda tympani and greater superficial petrosal terminals, both of the seventh nerve, overlap and are located rostral to the ninth (lingual-tonsilar IX) nerve and the tenth (superior laryngeal) nerve. (b) Distribution of electrophysiological responses to oral stimulation. Taste responses from the anterior oral cavity (ao), closed circles; taste responses from the posterior oral cavity (po), closed triangles; taste responses from the whole mouth, closed diamonds; responses to mechanical stimulation of the anterior oral cavity, open circles; responses to mechanical stimulation of the posterior oral cavity, open triangles. Caudal shaded areas indicate primary afferent terminals from the pharynx (ph), larynx (la), esophagus (es), stomach (st), and cecum (ce). (c) Differential, but overlapping terminations from the soft palate, closed circles; pharynx, open squares; esophagus, closed triangles; and stomach, open circles. The dashed line in (a) represents a parcellation of the NST into medial and lateral regions. DC and IV arrows indicate, respectively, the level of the dorsal cochlear nucleus, and union of the NST with the fourth ventrical medially. Reproduced from Norgren, R. 1995. Gustatory System. In: The Rat Nervous System (*ed.* G. Paxinos), pp. 751–771. Academic Press, with permission from Elsevier, as adapted from Travers, S. P. 1993. Orosensory Processing in Neural Systems of the Nucleus of Solitary Tract. In: Mechanisms of Taste Transduction (*eds.* S. A. Simon and S. D. Roper), pp. 339–424. CRC press.

in the rostrocaudal plane reflecting the different medullary entry points of the NST's cranial nerve inputs, from the rostral-most VII to the caudal-most X. Moreover, the pattern of gustatory inputs defines an oropharyngeal topography within the NST wherein the taste buds of different regions of the oropharyngeal cavity are represented centrally in a somatotopic arrangement. Cranial nerve VII-innervated buds are on the anterior tongue and on the apposing palate, the central endings of the nerve branches innervating these two fields are largely coincident and located at the rostral pole of the NST. Cranial nerve IX-innervated buds are on the posterior tongue, the nerve's gustatory endings are overlapping but immediately caudal to those of CN VII (Whitehead, M. C., 1988a; 1988b in hamster; May, O. L. and Hill, D. L., 2006, in rat). Cranial nerve X-innervated buds are farthest posterior (on the larynx), the nerve's endings are located farthest caudal in the gustatory NST.

Primary afferent inputs are also arranged with a gross modality-specific topography in that gustatory axons synapse in rostral levels of the NST, while general visceral ones synapse caudally. This rostrocaudal arrangement is related to the differential representation of these two broad functional categories of axon types in VII, IX, and X. Thus, for example, VII which contains taste but no general visceral axons synapses rostrally, X with some taste, but predominant general viscerosensory axons synapses caudally. At any particular rostrocaudal level of the NST, primary afferent endings are concentrated in some cell groups of the nucleus, light or absent in others, indicating that there are subdivisions within the nucleus that can be defined on the basis of cytoarchitecture and inputs (Figure 7). Taste primary afferent synapses, in particular, are concentrated in a centrally located cell grouping in the rostral half of the NST, termed the rostral central subdivision. They synapse to a lesser extent also in the rostral lateral subdivision. These two subdivisions, and others involved in higher order, lemniscal connections of the taste pathways, are characterized by differences in the densities, sizes, and shapes of constituent neurons. The functional segregation within the NST further extends to the general visceral inputs themselves, with different visceral organs being represented in different longitudinal domains (i.e., subdivisions) within the NST (Katz, D. M. and Karten, H. J., 1983; Altschuler, S. M. *et al.*, 1989).

4.11.3.1.2 Subdivisions and cell types

Cells of the NST, generally, are smaller than those that surround the nucleus, for example, in the vestibular nuclei above, or the reticular formation below. This feature and the nucleus' felt-like neuropil, evident in silver stains and as differentially heterochromatic Nissl staining, allow the boundaries of the NST to be readily drawn (Whitehead, M. C., 1988a; 1988b). Cell groupings within the NST give the nucleus a heterogeneous cytological organization (Figure 8). A number of investigators have subdivided the nucleus based on routine cell staining with the Nissl method. Most studies recognize medial and lateral differences in cell packing and have simply divided the nucleus at every rostrocaudal level into two parts, medial and lateral (see, e.g., Torvik, A., 1956 in rat; Beckstead, R. M. and Norgren, R., 1979 in monkey; Hamilton, R. B. and Norgren, R., 1984 in rat). In hamster, additional staining methods, most notably, the Golgi stain which shows the dendrites and axons of cells, provided evidence for a third area, the central subdivision, that is cytologically distinct and interposed between the medial and lateral subdivisions (Whitehead, M. C., 1988a; 1988b). Subsequent studies in rat have similarly identified the rostral central subdivision as the prominent zone of neural activation by gustatory inputs from the periphery (e.g., Harrer, M. I. and Travers, S. P., 1996; Travers, S. P. and Hu, H., 2000). This central area coincides with parts of the lateral and medial subdivisions of earlier parcellation schemes (Torvik, A., 1956; Beckstead, R. M. and Norgren, R., 1979).

The central subdivision of the NST is distinguished by cells that are relatively small and densely packed and that exhibit three types of dendritic morphologies (Figure 9). Elongate cells have ovoid cell bodies and dendrites that extend in the mediolateral plane. Tufted neurons have dendrites or dendritic branches with one predominant orientation, usually dorsally or ventrally. Stellate cells have rounded or polygonal cell bodies and dendrites that radiate in all directions. A variety of small stellate cell with lumpy, irregular dendrites and a very short, locally arborizing axons, i.e., a local circuit neuron, is also present. The dendrites of all three cell types bear spiny or pedunculated appendages.

Correlating the cytoarchitectonic subdivisions with the locations of taste nerve endings, labeled by application of tracers to gustatory branches of the facial (CN VII), glossopharyngeal (CN IX), and vagus (CN X) nerves, established that the taste primary afferent termination zone coincides with the

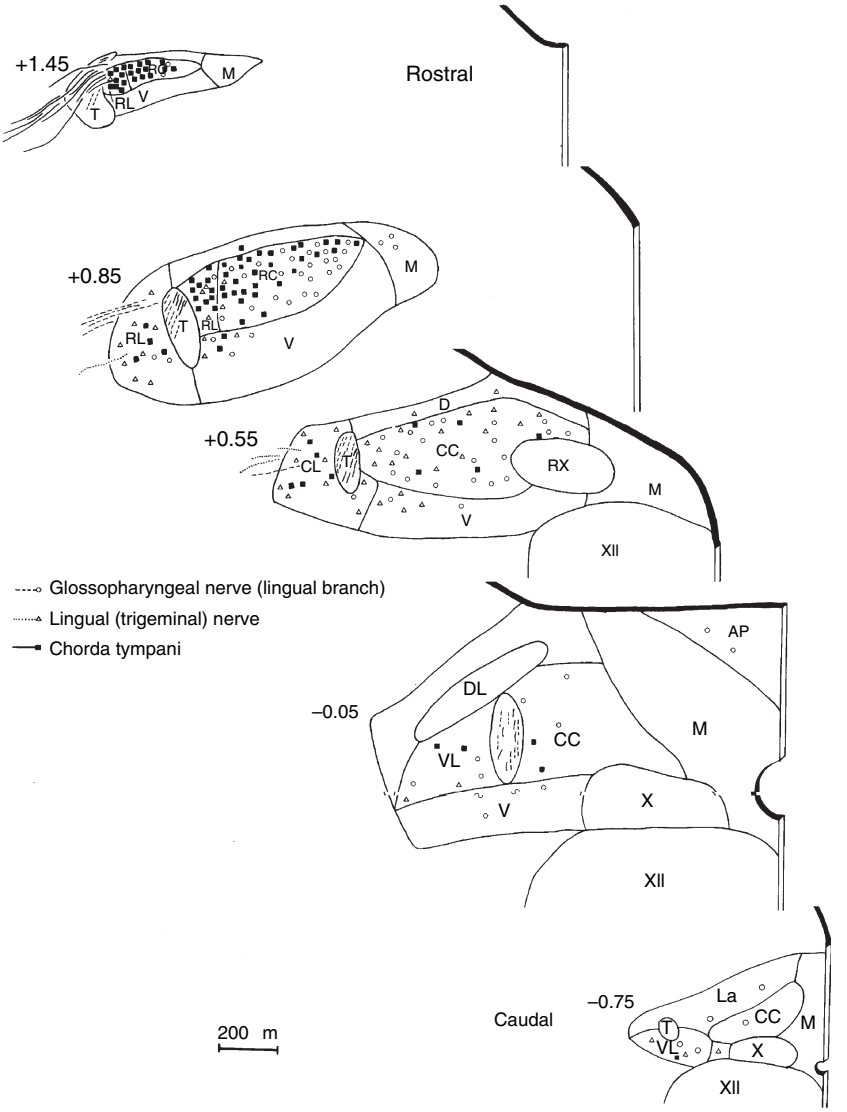

Figure 7 The NST in transverse sections showing the relationship of oral cavity inputs to cytoarchitectonic subdivisions in hamster (see Figure 8 for abbreviations). Taste afferent terminals from the anterior tongue (chorda tympani, closed squares) are concentrated in the rostral central subdivision; terminals from the posterior tongue (glossopharyngeal nerve, lingual branch, open circles) overlap but are densest more caudal than chorda ones in the rostral central subdivision. Nontaste, trigeminal inputs from the anterior tongue (lingual nerve, open triangles) overlap taste inputs but are concentrated in the rostral lateral subdivision. Numbers at left indicate distance (in mm) of each section from the obex. Reproduced from Whitehead M. C. (1988a; 1988b).

rostral central subdivision (Figure 7). The rostral lateral subdivision also received many taste endings, with fewer and fewer endings in the caudal central and caudal lateral subdivisions, respectively. Considering the entire extent and outlines of the NST, the distribution of all taste endings is to rostral and lateral regions of the nuclear complex.

The synaptic organization of taste inputs within the rostral central subdivision has been defined for the hamster (Whitehead, M. C., 1986; Brining, S. K. and Smith, S. K., 1996). Taste afferent endings, labeled with the marker horseradish peroxidase, were found to synapse *via* round vesicle-containing endings and asymmetrical membrane specializations primarily with small caliber dendrites and dendritic spines (Figure 10). Synapses of this type are likely excitatory. The taste afferent endings synapse in association with other, presumably nonprimary, endings. Some of

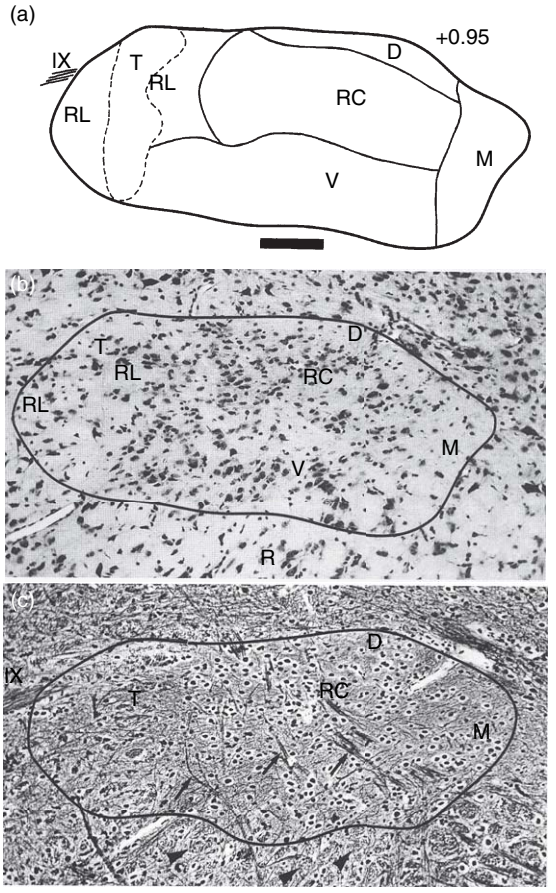

Figure 8 Cytoarchitectonic subdivisions of the NST in transverse sections at the level of the glossopharyngeal sensory nerve root in hamster (level similar to the second from the top in Figure 7). (a) Drawing of the outlines of subdivisions in the Nissl-stained section (b) The rostral central subdivision (RC) is characterized by smaller, densely packed, round, oval, and elongate cells; the medial subdivision (M) is sparsely cellular; the ventral subdivision (V) has larger somewhat clustered cells; the rostral lateral subdivision is moderately cellular and has the solitary tract (T) embedded within it. (c) Reduced silver-stained section adjacent to that in (b) showing the felt-like neuropil of the NST and thick fibers of passage arcing from the vestibular nuclei dorsal to the NST through the rostral central (RC) and ventral (V) subdivisions. Number at upper right indicates distance (in mm) of the sections from the obex. Reproduced from Whitehead M. C. (1988a; 1988b).

these nonprimary endings contain flat vesicles and engage in symmetrical synaptic junctions indicative of inhibitory synapses. The presence of presumed inhibitory endings is consistent with the identification of GABA-ergic cells and endings in the rostral NST (Lasiter, P. S. and Kachele, D. L., 1988; King, M. S., 2003) and similar small neurons in the rostral central subdivision that have locally arborizing axons, that is, inhibitory local circuit neurons. The complex synaptic milieu of taste endings on second-order neuronal dendrites, distant from their cell bodies, allows for modulation of taste-elicted activity in the afferent endings themselves or in the second-order neurons by other inputs, including interneuronal ones.

Other subdivisions border the rostral central subdivision (see, e.g., Figure 8). They differ in the extent to which they are involved in taste-related pathways (Whitehead, M. C., 1988a; 1988b). Thus, there are ventral and medial subdivisions bordering the rostral central subdivision which receive sparse taste afferent input (Figure 7). Similarly, caudally in the NST, subdivisions include caudal central, ventral medial, and ventrolateral which receive sparse taste input, but receive other inputs including general visceral primary afferent axonal endings from internal organs (Figure 6). These caudal areas of the NST project to the rostral areas and allow for interoceptive (e.g., gastrointestinal) and oral (taste) interactions within the NST (Karimnamazi, H. *et al.*, 2002).

4.11.3.2 Brainstem Reflex Connections

Taste stimulation elicits highly stereotyped oromotor behaviors that effect ingestion of palatable compounds (e.g., licking of sweet tastants) and rejection of aversive tastes (e.g., tongue protrusion and gaping to eject bitter, potentially poisonous, compounds) (Grill, H. J. and Norgren, R., 1978a; 1978b). These motor behaviors result from activation and modulation of local gustatory sensory–motor reflex pathways involving short distance connections confined within the medulla. These local, intramedullary pathways and the neurons they engage have, to some level of detail, been defined anatomically and functionally. The rostral (gustatory) NST projects heavily to the nearby, subjacent reticular formation (Travers, J. B., 1988; Beckman, M. E. and Whitehead, M. E., 1991) (Figures 11 and 12). The reticular formation, in turn, projects to motor nuclei involved in oromotor behaviors (Travers, J. B. and Norgren, R., 1983) (Figures 12 and 13). These include the hypoglossal nucleus for tongue movements, the trigeminal motor nucleus for jaw movements, the facial motor nucleus for facial movements, and nucleus ambiguus for pharyngeal movements associated with swallowing. Though less well studied because of the small size of the NST and the difficulty of mapping short connections, there are intranuclear connections that ultimately influence reticular and oromotor neuronal responses to tastes. These intranuclear

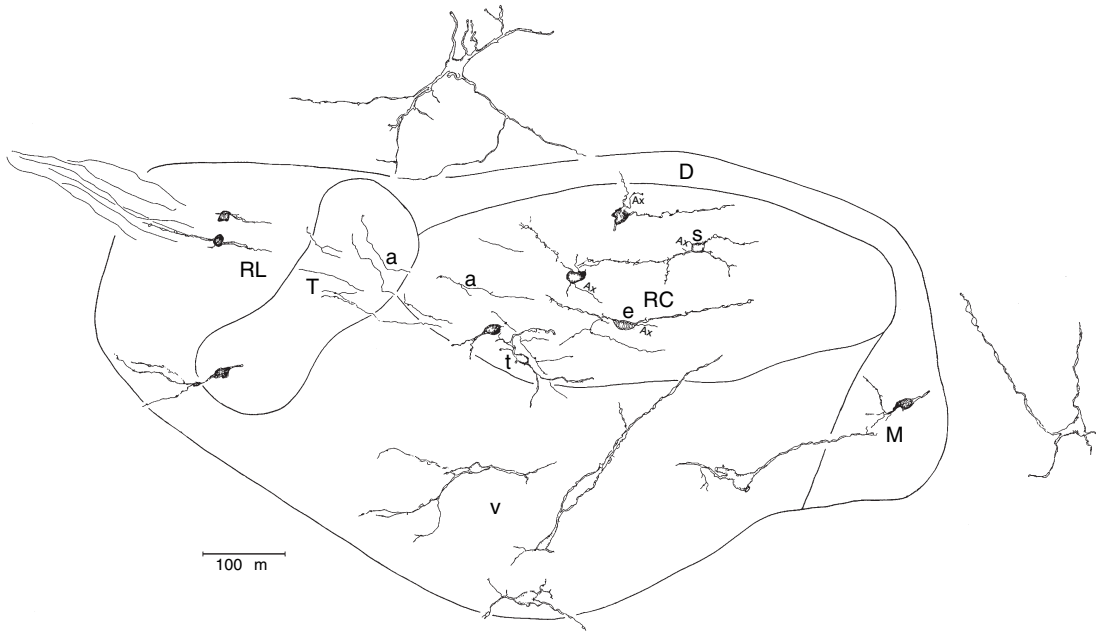

Figure 9 Cell types and axons (Golgi-Cox method) of the rostral NST in hamster at the level of the glossopharyngeal nerve root (fibers at upper left) (level similar to that in Figure 8). Primary afferent axons of the nerve root and solitary tract (a) parallel the dendrites of elongate cells in the rostral lateral subdivision and in the rostral central subdivision (e). A stellate cell (s) also has mediolaterally oriented dendrites; t, tufted neuron. Cells of the ventral subdivision are larger with longer dendrites than those of other subdivisions. Larger still, with more elaborate dendritic branching, are the cells dorsal (vestibular) and medial to the NST which are drawn for comparison. (Abbreviations of subdivisions as in Figure 8.) Reproduced from Whitehead M. C. (1988a; 1988b).

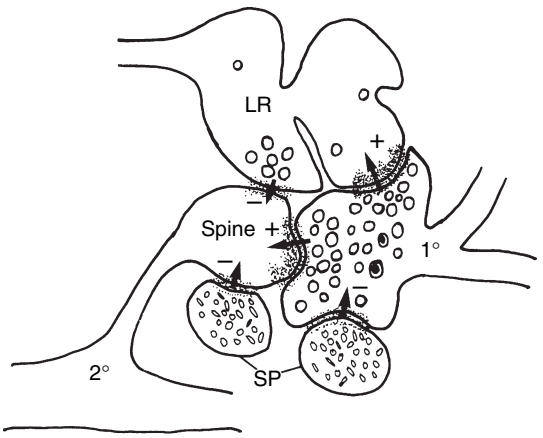

Figure 10 A synaptic circuit for taste (facial, including chorda tympani) primary afferent endings in the rostral central subdivision of the NST in hamster. Taste endings (1°) synapse on dendritic spines of second-order neurons (2°) and on other (possibly dendritic) endings (LR), which in turn influence transmission by means of LR (dendro?)-dendritic synapse. Transmission through the taste axon-second-order neuron circuit is also modulated pre- and postsynaptically by SP axonal endings with flat vesicles and symmetrical synaptic junctions. The signs (+) and (−) indicate possible excitatory and inhibitory influences. Reproduced from Whitehead, M.C. 1986. Anatomy of the gustatory system in the hamster: synaptology of facial afferent terminals in the solitary nucleus. J. Comp. Neurol. 244, 72–85.

connections appear to differentially involve the cytoarchitectonic subdivisions.

Small neuroanatomical tracer injections confined to the rostral NST and heavily involving the rostral central subdivision demonstrate that there are intra-NST projections from this taste-afferent recipient region to ventral and medial portions of the NST at more caudal levels. Thus, the medial and ventral subdivisions at intermediate rostrocaudal levels of the nucleus receive heavy input from the rostral central NST. Outside the NST, heavy axonal projections terminate in the parvicellular medullary reticular formation immediately ventral to the NST (Beckman, M. E. and Whitehead, M. C., 1991) (Figures 11 and 12). The injection sites yielding these local projections, while small, invariably include the ventral subdivision, so it is difficult to resolve all the possible short distance connections. Nevertheless, the evidence to date is consistent with a pathway whereby neurons in the rostral central subdivision are activated by taste-elicited impulses arriving from primary afferent synapses (Figure 12). In turn, many of these first-order central neurons project to other regions of the NST, including to the ventral subdivision. The ventral subdivision (and, perhaps, the rostral central

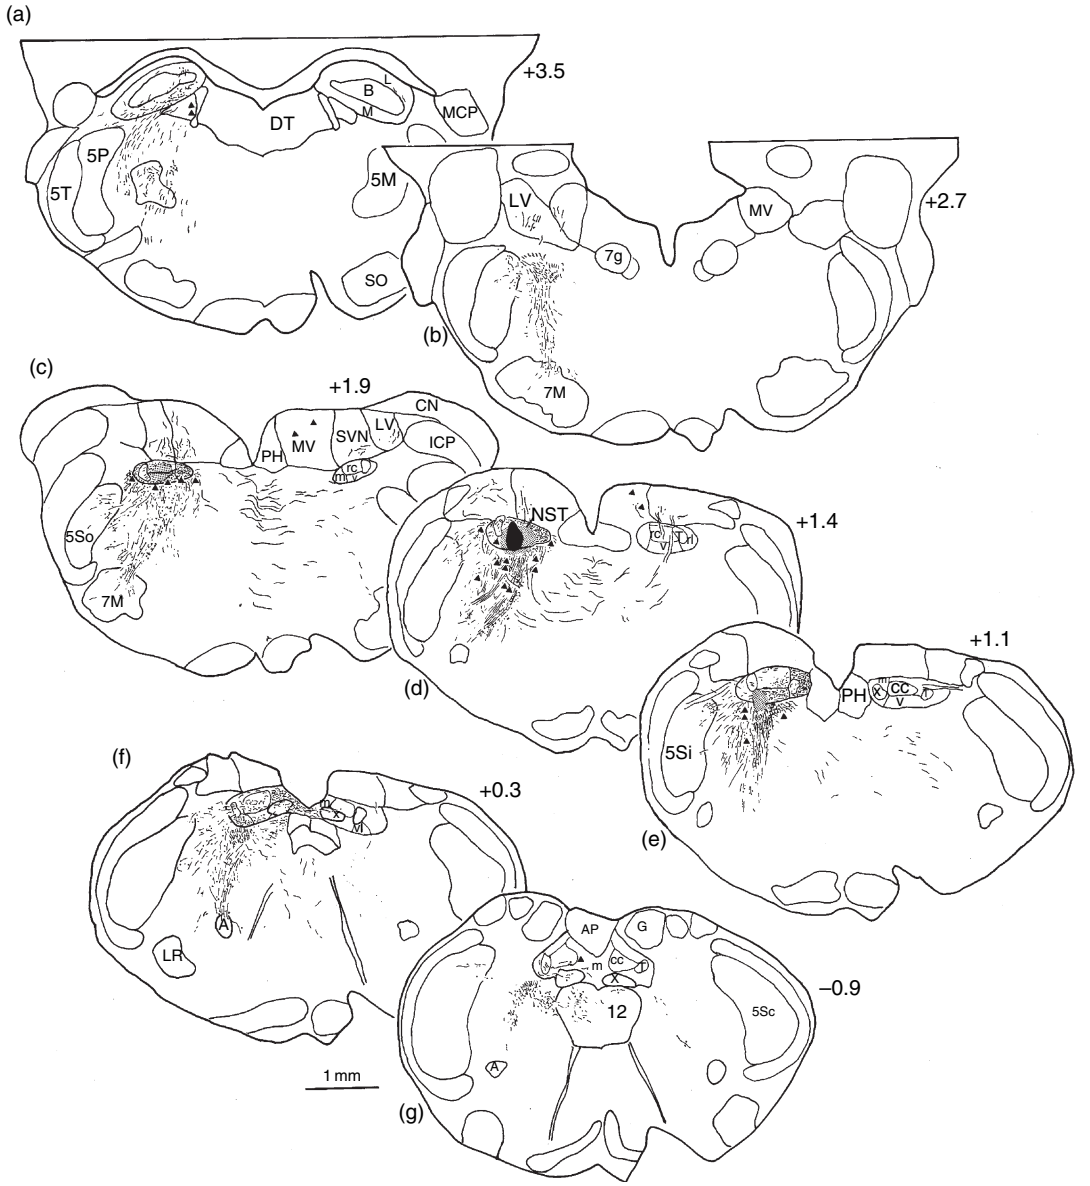

Figure 11 Ascending (lemniscal) projections and local (reflex) projections from the rostral NST in hamster seen after an injection of neuroanatomical tracer (HRP) into the gustatory domain (center of injection site at same level as in Figure 8, includes rostral central and ventral subdivisions). Letters identifying nuclei are shown on the right side of the brain in order to best see labeled endings (dots) on the right. Ascending axons from the NST terminate rostrally in the medial PBN (B-M) and sparsely in the trigeminal motor nucleus (5M). Local and caudally directed labeled axons terminate in the reticular formation (RF) ventral to the NST and lateral to the hypoglossal nucleus (12) and, sparsely, within the hypoglossal, vagal (X) and facial (7M) motor nuclei. Nucleus ambiguus (A). Intra-NST label extends caudally to the level of the area postrema (AP) and is concentrated in the medial (m) and ventral (v) subdivisions. Triangles indicate retrogradely labeled neuronal cell bodies. Numbers at right indicate distance (in mm) of each section from the obex. Reproduced from Beckman, M. E. and Whitehead, M. C. 1991. Intramedullary connections of the nucleus of the solitary tract in the hamster. Brain Res. 557, 265–279, with permission from Elsevier.

subdivision, directly) projects heavily to the parvocellular reticular formation (Beckman, M. E. and Whitehead, M. C., 1991) which, in turn, projects heavily to all the oromotor nuclei (Travers, J. B. and Norgren, R., 1983; Travers, J. B., 1988).

Combining Fos labeling during taste stimulation with neuroanatomical retrograde labeling of cells that project to the parvocellular reticular formation revealed a pattern consistent with a role for ventrally projecting neurons and of the ventral NST

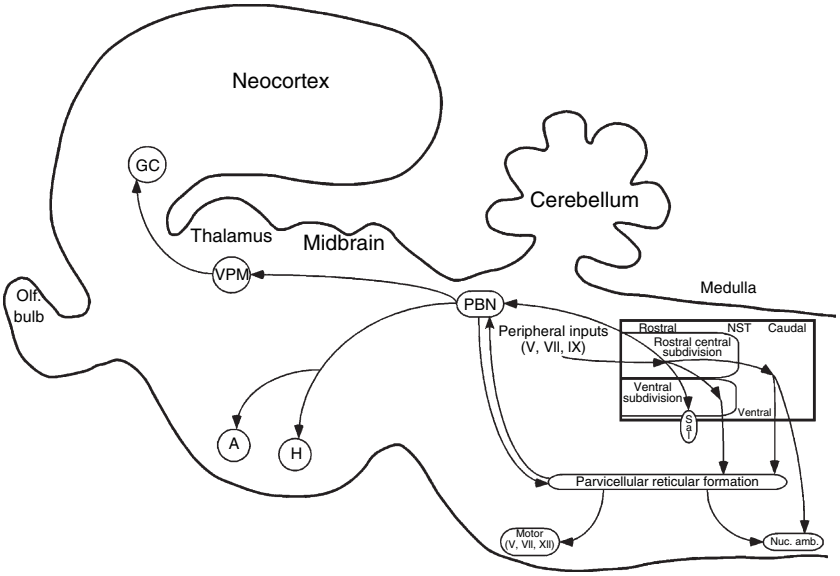

Figure 12 Local and ascending pathways of the mammalian central gustatory system diagrammed on a sagittal view of the brain. The local (reflex) pathway involves cells in the rostral central subdivision of the NST that receive input from primary afferent peripheral fibers. These cells can project to the ventral subdivision of the NST either directly or via the caudal NST. The ventral subdivision, in turn, projects to the reticular formation. Finally, the parvicellular reticular formation projects to nucleus ambiguus and the oral motor nuclei (motor V, VII, XII). Local projections also involve the salivatory nuclei (Sal). The major ascending (lemniscal) pathway involves cells of the rostral central subdivision that project to the parabrachial nucleus of the pons (PBN) which, in turn, projects to the parvocellular ventroposteromedial nucleus of the thalamus (VPM). This gustatory part of the thalamus projects to agranular insular cortex (GC). A second ascending pathway involves a projection from the PBN to the basal forebrain (principally to the lateral hypothalamus (H), amygdala (A), and bed nucleus of the stria terminalis (not shown).

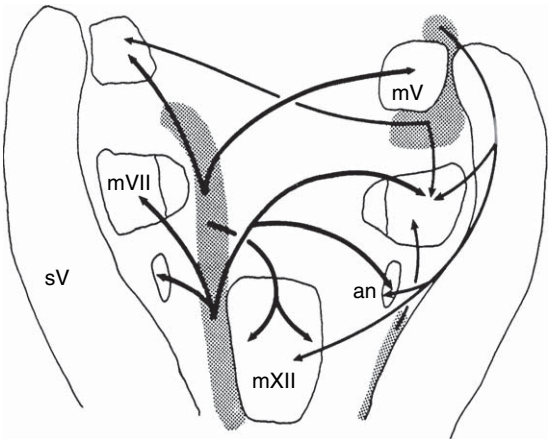

Figure 13 Diagram (horizontal plane) of the regions of the reticular formation (in gray cross-hatching) that project to the oral motor nuclei in rat. The reticular-motor projection neurons are located throughout the length of the medulla, including the area below the NST as in Figure 11. Projections are to nucleus ambiguus (an), the hypoglossal nucleus (mXII), the facial (mVII), and trigeminal (mV) motor nuclei bilaterally. Reproduced from Travers, J. B., and Norgren, R. 1983. Afferent projections to the oral motor nuclei in the rat. J. Comp. Neurol. 220, 280–298.

subdivision in influencing premotor reticular formation neurons (Travers, S. P. and Hu, H., 2000). Electrical stimulation of the second-order gustatory nucleus (the PBN, in rat) activates cells in the ventral NST and elicits oromotor behaviors, illustrating an influence of descending impulses from the second-order taste center on the medullary reflex pathway (King, M. S. *et al.*, 2003).

4.11.3.2.1 Topography of taste quality

Functional evidence that the rostral central and lateral subdivisions of the rostral NST are principally involved in taste information processing derives from experiments seeking to determine whether taste quality is represented topographically in the NST. Electrophysiological recordings, either single or multiunit methods, have not, despite many investigations, revealed a consistent or clear-cut chemotopic organization (e.g., Pfaffmann, C. *et al.*, 1961; Scott, T. R. *et al.*, 1986; Mistretta, C. M., 1988). Nevertheless, reconstructions of sites of taste-activated neurons in relation to subdivisions of the NST localize most of them, in hamster, to the rostral central and rostral lateral subdivisions (McPheeters, M. *et al*, 1990;

Whitehead, M. C. *et al.*, 1993). More recently, anatomical localization of NST cells activated by particular taste stimuli was accomplished with immunocytochemistry for Fos, the protein product of the c-fos gene. Fos-positive cells attributable to taste stimulation were differentially concentrated in the rostral central subdivision (Harrer, M. I. and Travers, S. P., 1996, in rat). Although no straightforward chemotopography was evident and sucrose and quinine activated cells were intermingled, the latter were concentrated medially within the central subdivision evidence for a crude chemotopography as has been suggested in earlier electrophysiological studies (Halpern, B. P. and Nelson, L. M. 1965) (Figure 14). This crude chemotopy may reflect the differential distribution of different taste receptors within the oral cavity (Chandrashekar, J. *et al.*, 2006) making it difficult to distinguish a chemotopic map from an orotopic one.

4.11.3.3 Lemniscal Pathway

The lemniscal pathway in the mammalian gustatory system extends from the NST through the thalamus to the cerebral cortex for perception (Figure 12). In rodents, but not primates, all information ascending to the thalamocortical system undergoes an obligatory synaptic interruption in the PBN of the pons. The PBN is also a site of synaptic interruption in the pathway leading to the basal forebrain (see Section 4.11.3.4).

The projection from the NST to the PBN is massive and involves axons originating from cells in rostral and caudal levels of the medullary nucleus (Norgren, R. and Leonard, C. M., 1973; Norgren, R., 1978; Beckstead, R. M. *et al.*, 1980; Travers, J. B., 1988). Thus, both taste and general viscerosensory impulses project to the pons. The pontine representations of taste and nontaste (e.g., gastric) signals are separated among the subdivisions of the PBN (Karimnamazi, H. *et al.*, 2002). The gustatory PBN projection neurons of the NST have been identified and are predominantly located in the rostral central subdivision, the same region receiving densest taste inputs from the periphery (Whitehead, M. C., 1990). Specific cell types in the rostral central subdivision that project to the PBN, in hamster, are the elongate and stellate cells. These projection neurons, back-

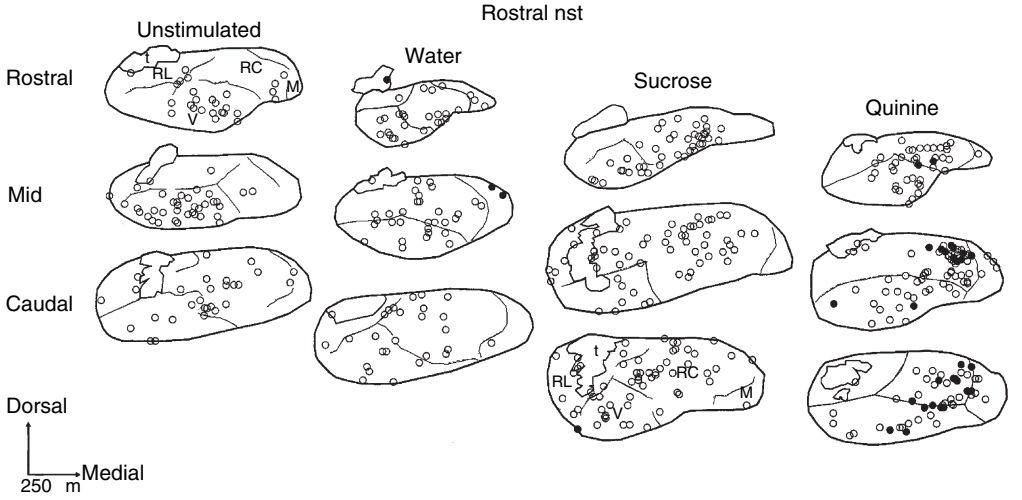

Figure 14 Distribution of cells immuno-positive for Fos elicited by two qualitatively and hedonically distinct taste stimuli, sucrose and quinine, within the rostral nucleus of the solitary tract of rat. Three anteroposterior levels in the transverse plane are shown for one animal from each of four stimulus conditions. Thin lines depict boundaries of cytoarchitectonic subdivisions (abbreviations as in Figure 8). Filled and open circles indicate intensely and moderately stained nuclei, respectively, of Fos-positive cells. Taste-stimulated animals had more numerous Fos-positive cells than the water and unstimulated animals, particularly in the rostral central subdivision. Within the central subdivision, Fos-positive neurons following quinine stimulation were concentrated medially; positive neurons following sucrose stimulation were distributed more evenly along the mediolateral axis. Despite their differential distribution, sucrose- and quinine-activated neurons were intermingled. Reproduced from Harrer, M. I. and Travers, S .P. 1996. Topographic organization of Fos-like immunoreactivity in the rostral nucleus of the solitary tract evoked by gustatory stimulation with sucrose and quinine. Brain Res. 711, 125–137, with permission from Elsevier.

filled with neuroanatomical markers, have been analyzed with the electron microscope to establish that they receive primary-like synaptic inputs (Whitehead, M. C., 1993). Therefore, the NST–PBN gustatory projection neurons correspond to first-order central neurons that are contacted directly by taste afferent endings from the periphery.

4.11.3.3.1 Second-order (parabrachial) nucleus

The PBN is a complex of different cytoarchitectonic subdivisions that surround the brachium conjunctivum (Fulwiler, C. E. and Saper, C. B., 1984; Halsell, C. B. and Frank, M. E., 1989). These subdivisions are generally grouped into either the lateral division, dorsal and lateral to the brachium conjunctivum and bordering the external surface of the pons, or the medial division, medial to the brachium. Gustatory-responsive neurons have been localized predominantly in the medial division, while general viscerosensory neurons have been localized in the lateral division. Anatomical studies support this functional parcellation: the medial PBN receives input from the rostral, gustatory NST; the lateral PBN receives input from the caudal, viscerosensory NST. In particular, the medial PBN, predominantly its caudal and ventral parts, receives projections from cells of the rostral central and rostral lateral subdivisions of the NST. The lateral PBN, predominantly its intermediate and rostral–dorsal parts, receives projections from the caudal central and medial subdivisions of the NST (Whitehead, M. C., 1990). PBN projection cells of the rostral NST, that is, gustatory cells of the ascending viscerosensory system, are more numerous than PBN projection cells of the caudal NST, that is, general viscerosensory cells. The pontine projections are predominantly ipsilateral, although a small minority of NST neurons project to the contralateral PBN. The most prominent subdivision within the PBN receiving input from the gustatory NST is the medial subdivision, especially at caudal levels of the nucleus. Gustatory projections also extend, but lightly, into the medial part of the lateral subdivision. Within the gustatory PBN neurons responsive to anterior and posterior regions of the oral cavity are located in different cytoarchitectonic subdivisions, evidence for at least a gross orotopy at this second-order level of the ascending taste system in mammals (Halsell, C. B. and Travers, S. P., 1997), just as in fish (see Section 4.11.3.2).

4.11.3.3.2 Third-order (thalamic) nucleus and gustatory cortex

In contrast with other lemniscal sensory systems in which the thalamus receives input directly from the medulla, in the taste system, excepting for Old World monkeys (Hamilton, R. B. *et al.*, 1985), the thalamus receives input from second-order central neurons in the PBN (Figure 12). The PBN-thalamus projection terminates in a small medial-most sliver of the ventroposteromedial thalamic nucleus (VPM) (Norgren, R. and Leonard, C. M., 1973). The VPM generally processes information about somatosensation of the face relayed rostrally from first-order central neurons in the trigeminal sensory nucleus of the brainstem. The gustatory-specific thalamic nucleus, the VPMgus parvocellularis (pc), is the medial-most part of the VPM. Thus, functions are topographically represented; third-order taste neurons lie just medial to second-order general sensory neurons processing, for example, touch and temperature information from the face, mouth, and tongue. Indeed, taste and lingual touch neurons occur side by side in the VPM. The VPMgus pc projects to gustatory neocortex (Figure 12).

Gustatory neocortex lies in the insular region, dorsal to the rhinal fissure. This region, identified as taste-responsive (Kosar, E. *et al.*, 1986 in rat, Wehby, R. G. and London, J. A., 1995 in hamster), is characterized cytoarchitectonically as being agranular or dysgranular, that is, lacking a well-defined layer IV (Kosar, E. *et al.*, 1986) As in thalamus, somatotopy is evident in the cortical taste area. Taste neurons are located in a region bordering (ventral to) somatosensory primary cortical neurons representing the tongue, which in turn are just ventral to mouth and face representations (Norgren, R. and Wolf, G., 1975).

4.11.3.4 Basal Forebrain and Descending Pathways

In addition to the thalamocortical gustatory pathway, there are dense ascending taste projections to the basal forebrain (Figure 12). Axons from cells in the NST and PBN terminate heavily in the lateral hypothalamus, the amygdala, and the bed nucleus of the stria terminalis (Saper, C. B., 1982; Halsell, C. B., 1992; Nakashima, M. *et al.*, 2000; Pritchard, T. C. *et al.*, 2000). These limbic projections likely mediate autonomic functions related to activation of the taste system and hedonic aspects of feeding. These limbic regions, together with the pontine and

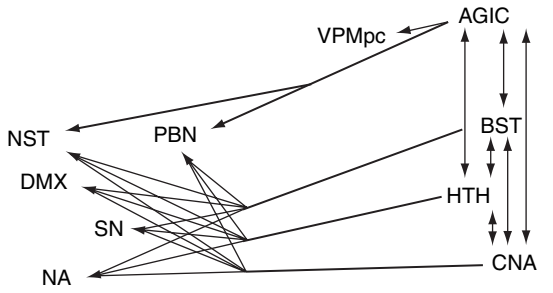

Figure 15 Descending pathways of the mammalian gustatory system schematically represented in the sagittal plane (rostral is at the right). Lines with single arrowheads indicate major long, descending forebrain projections to the hindbrain. Forebrain regions include agranular insular (gustatory) cortex (AGIC), the bed nucleus of the stria terminalis (BST), the hypothalamus (HTH), and the central nucleus of the amygdala (CNA). Hindbrain nuclei that receive terminals from the forebrain gustatory-related areas are the NST, the PBN, the dorsal motor vagal nucleus (DMX), the salivatory nuclei (SN) and nucleus ambiguus (NA). Double arrows indicate local forebrain reciprocal interconnections. Reproduced from Norgren, R. 1985. Taste and the autonomic nervous system. Chem. Senses 10, 143 –161, by permission of Oxford University Press.

thalamocortical areas, are reciprocally interconnected with each other (Figure 15).

Descending axons from forebrain, taste-related areas also synapse in the NST (Figure 15). Projections from gustatory cortex to the taste region of the NST are particularly dense and terminate heavily in the rostral central subdivision, the same subnuclear zone that contains primary afferent synapse and PBN projection neurons (Whitehead, M. C. *et al.*, 2000). Thus, descending impulses from cortex are positioned to influence the first central taste area. In addition, there are descending connections from gustatory cortex to the amygdala, the hypothalamus, and the PBN (Reep, R. L. and Winans, S. S., 1982). These areas, therefore, interconnect both the gustatory NST and the gustatory neocortex. The interconnections are quite precise and related to gustatory functions (Karimnamazi, H. and Travers, J. B., 1998; Cho, Y. K. *et al.*, 2003). Thus, gustatory cortex receives projections from the lateral hypothalamus, the same region that sends descending axons to the rostral NST. Cortical connections with the PBN are reciprocal and most heavily involve the medial PBN, the major termination site for axons ascending from the rostral NST, and a site originating projections back to the rostral NST. The gustatory cortex projects heavily to the central amygdaloid nucleus, a site of origin of amygdalofugal axons that project to the rostral NST. The anterior and basolateral amygdala are also reciprocally connected with gustatory cortex (Reep, R. L. and Winans, S. S., 1982; Whitehead, M. C. *et al.*, 2000). By these connections, the forebrain, particularly the limbic system, has access to both taste information and regions involved in autonomic outflow, for example, for energy and hydromineral regulation (Norgren, R., 1985; Grill, H. J. and Kaplan, J. M., 2002).

4.11.4 Conclusion

In summary, the general organization of the central gustatory pathways is similar in mammals and teleost fishes. This implies that this organizational scheme evolved early in vertebrate phylogeny. Not only are the broad patterns of connectivity similar between these disparate groups but also the details of connectivity and neurotransmitters. For example, glutamate acting on ionotropic glutamate receptors is the neurotransmitter at the first synapse of the system within the medullary gustatory nuclei (Bradley, R. M. *et al.*, 1996; Smeraski, C. A. *et al.*, 1996; Li, C. S. and Smith, D. V., 1997; Smeraski, C. A. *et al.*, 1998; 1999). Different cell populations in the primary taste relay give rise to the reflex connections and the ascending fiber systems (Finger, T. E., 1978; Whitehead, M. C., 1990; Halsell, C. B. *et al.*, 1996; Gill, C. F. *et al.*, 1999). In addition, neurons of the secondary gustatory nucleus can either project widely to both lemniscal and limbic targets or may show more restricted projections to the lemniscal nuclei only (Nomura, S. *et al.*, 1979; Halsell, C. B., 1992; Lamb, C. F. and Finger, T. E., 1996). Taken together, these findings indicate that the basic organization of the central gustatory system is phylogenetically old and stable through evolution. This stability may reflect the crucial nature of this system for survival.

4.12.1 Introduction

In general there are two groups of investigators studying the nucleus of the solitary tract (NST). The largest group investigates the caudal nucleus that is involved in control of the digestive, cardiovascular, and respiratory systems. A much smaller cadre of investigators study the rostral nucleus (rNST) that forms the first central relay in the central taste pathway. Gustatory, tactile, and thermal information is relayed from the oral cavity via the chorda tympani and greater superficial petrosal branches of the facial nerve and the lingual branch of the glossopharyngeal nerve to the rNST, sometimes referred to as the gustatory NST. From there information either passes to rostral brain areas or to brainstem motor systems involved in facial and masticatory movements or the secretion of saliva.

Synaptic processing is involved at all stages of the pathway and investigators of both the rostral and caudal NST have extensively studied the synapses using anatomical, neurophysiological, and immunocytochemical techniques. The present review is restricted to the current knowledge of the neurotransmitters involved in the taste pathway which has been the focus of reviews (Bradley, R. M. *et al.*, 1996; Bradley, R. M. and Grabauskas, G., 1998; Smith, D. V. *et al.*, 1998). Neurotransmitters involved in the caudal NST have been extensively reviewed (Van Giersbergen, P. L. M. *et al.*, 1992; Andresen, M. C. and Kunze, D. L., 1994; Lawrence, A. J. and Jarrott, B., 1996) and whereas there are similarities between both the rostral and caudal divisions of the NST there are significant differences. While these differences often reflect true differences in neurotransmitter expression, they may also be due to the fact that investigators studying a particular neurotransmitter restrict the investigation to either the caudal or rostral division. Moreover it is not always possible in investigations using coronal sections to determine how far rostral in the NST the sections are studied (e.g., see Ambalavanar, R. *et al.*, 1998; Saha, S. *et al.*, 2001) even though the title of the reports implies that the whole NST is being investigated. When investigators use horizontal sections of the entire extent of the NST differences in neurotransmitter distribution become evident (see Davis, B. J. and Jang, T., 1988).

4.12.2 Neurotransmitters in the Sensory Ganglia Involved in Transmission of Taste Information

Gustatory information derived from taste receptor cells is conveyed to the first central relay in the taste pathway via afferent sensory fibers. The cell bodies of these fibers are collected in peripheral sensory ganglia which include the geniculate (GG, facial nerve VII), petrosal (PG, glossopharyngeal IX), and nodose ganglia (NG, vagus nerve X). The neurotransmitter composition of the PG and NG has been studied using immunocytochemical techniques and these ganglia contain glutamate, substance P (SP), tyrosine hydroxylase, vasoactive intestinal polypeptide, calcitonin gene-related peptide, galanin, and aspartate

(Helke, C. J. and Hill, K. M., 1988; Helke. C. J. and Niederer, A. J., 1990; Czyzyk-Kreska, M. F. *et al.*, 1991; Helke, C. J. and Rabchevsky, A., 1991; Ichikawa, H. *et al.*, 1991; Finley, J. C. W. *et al.*, 1992; Okada, J. and Miura, M., 1992). No similar immunocytochemical survey has been undertaken for the GG. However, because afferent sensory neurons with cell bodies in the PG and GG supply a heterogeneous population of receptors, retrograde tracing techniques have been used to isolate the neurons that innervate taste buds for detailed investigation. Neurons in the GG and PG supplying the tongue, fluorescently labeled with either Fluorogold or true blue, were immunoreacted for glutamate receptors (Caicedo, A. *et al.*, 2004) or acutely dissociated and analyzed with patch-clamp recording (King, M. S. and Bradley, R. M., 2000; Koga, T. and Bradley, R. M., 2000). The pharmacological properties of neurons of the NG innervating laryngeal taste buds have not been determined.

There were significant differences in the response of PG and GG gustatory neurons to the application of acetylcholine (ACh), serotonin (5-HT), SP, and gamma-aminobutyric acid (GABA). Whereas PG neurons responded to ACh, serotonin, SP, and GABA, GG neurons only responded to SP and GABA (Koga, T. and Bradley, R. M., 2000; Figure 1).

Gustatory neurons of the GG have been examined for their expression and response to glutamate receptor agonists. Ionotropic glutamate receptors are divided into two major groups based on their sensitivity to the agonists *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA). Dissociated GG taste neurons responded to application of both agonists (King, M. S. and Bradley, R. M., 2000; Figure 2). By using antibodies to NMDA and AMPA receptor subunits, Caicedo A. *et al.* (2004) were able to demonstrate that gustatory neurons in the GG were strongly immunoreactive for GluR2/3, GluR4, and NR1 subunits suggesting that putative AMPA receptors are mainly composed of GluR3 and GluR4 subunits while NMDA receptors consist of NR1 receptor subunits.

4.12.3 Neurotransmitters in the Rostral Nucleus of the Solitary Tract Involved in Processing of Taste Information

Both anatomical and electrophysiological techniques have been used to define the neurotransmitters and neuromodulators and their receptors within the rNST. Glutamate and GABA have been shown to play a role in synaptic transmission in the rNST. Glutamate is the afferent excitatory transmitter released from gustatory afferent terminals (Wang, L. and Bradley, R. M., 1995; Li, C. S. and Smith, D. V., 1997) and is contained in neurons of the rNST (Sweazey, R. D., 1995). GABA immunoreactivity is present in the rNST, primarily contained in small ovoid neurons (Lasiter, P. S. and Kachele, D. L., 1988; Davis, B. J., 1993; Sweazey, R. D., 1996; Leonard, N. L. *et al.*, 1999). Electrophysiological recordings in brain slices indicate that neuron of the rNST express both AMPA and NMDA receptors as well as $GABA_A$ and $GABA_B$ receptors (Liu, H. *et al.*, 1993; Wang, L. and Bradley, R. M., 1993; Bradley, R. M. *et al.*, 1996; Li, C. S. and Smith, D. V., 1997; Figure 2). The brainstem slice experiments all suggest that rNST neurons are under tonic GABAergic inhibition. This was directly tested *in vivo* on taste-responsive neurons in which the spontaneous activity was suppressed in a concentration-dependent manner by microinjection of GABA (Smith, D. V. and Li, C. S., 1998).

The distribution of glutamate and GABA receptors in the rNST is not uniform. AMPA and NMDA receptors are concentrated in the rostral central division of the rNST which receives most of the primary afferent input (Whitehead, M. C., 1988). In contrast, GABA is more uniformly distributed throughout the rNST (King, M. S., 2003). These differences in distribution of the glutamate and GABA receptors are thought to represent their different roles in gustatory processing, glutamate being involved in excitatory input from afferent taste fibers, and GABA mediating generalized tonic inhibition of the whole rNST.

Study of rNST synaptic potentials reveals that they consist of a complex mixture of excitatory and inhibitory potentials. The synaptic potentials result from excitatory afferent input mediated by glutamate and inhibitory transmission is mediated primarily at $GABA_A$ synapses (Grabauskas, G. and Bradley, R. M., 1996). By eliminating the excitatory component with glutamate receptor blockers the inhibitory component can be isolated, allowing the study of pure inhibitory postsynaptic potentials (IPSPs) in rNST. In addition, instead of using single-shock stimuli to investigate synaptic potentials, trains of stimuli (tetanic stimulation) that mimic the frequency of afferent input to the rNST evoked by gustatory stimulation reveals additional characteristics of inhibitory activity in the rNST. Tetanic stimulation at frequencies of 10–30 Hz resulted in sustained hyperpolarizing IPSPs that could be blocked by the $GABA_A$

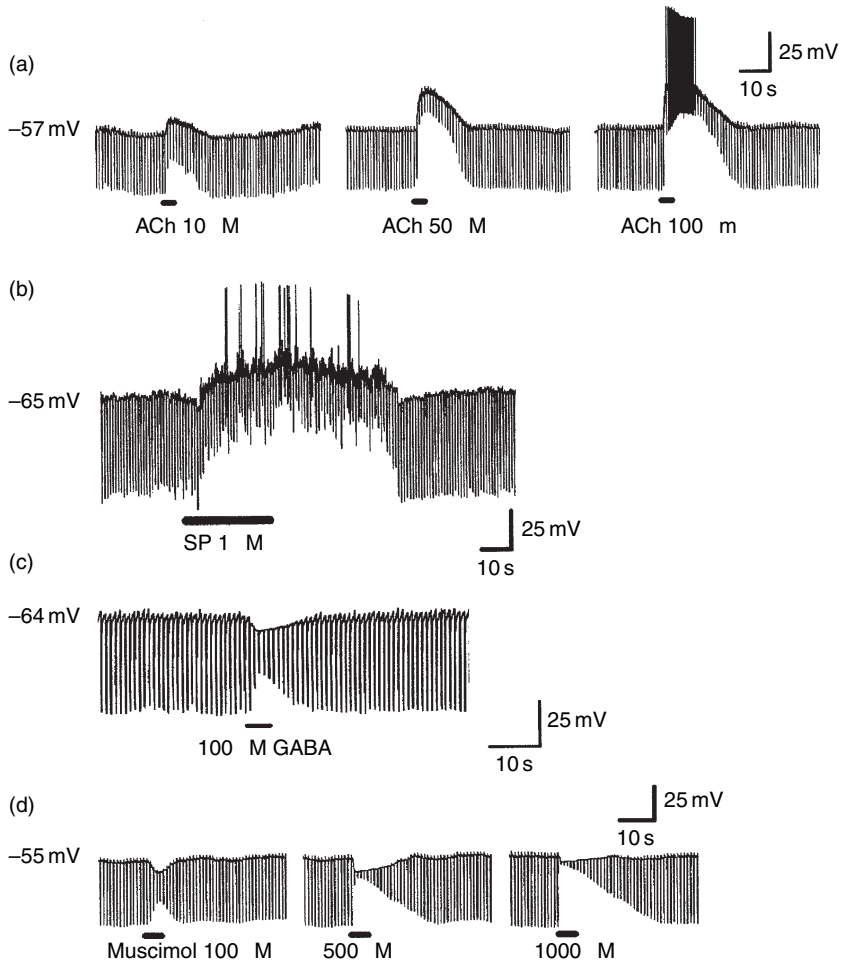

Figure 1 Voltage responses recorded from petrosal (PG) and geniculate ganglion (GG) neurons innervating the tongue to hyperpolarizing injections of −100 pA, 100 ms current pulses. (a) Membrane responses of a PG neuron to a 5 s application (bar) of increasing concentrations of acetylcholine (ACh). The ACh application induced membrane depolarization accompanied by a decrease in input resistance. The response is dose-dependent and returns to control levels within 30 s after termination of application. The depolarization resulting from the highest concentration of ACh initiated a burst of action potentials. (b) Membrane response of a PG neuron to a 5 s application (bar) of substance P (SP). In this neuron SP application depolarized the neuron and initiated the production of action potentials. (c) Membrane response of a GG neuron to a 5 s application (bar) of gamma-aminobutyric acid (GABA). In this neuron GABA application hyperpolarized the neuron with a decrease in input resistance. (d) Membrane responses of a PG neuron to a 5 s application (bar) of increasing concentrations of the $GABA_A$ receptor agonist muscimol. The mucimol application induced dose-dependent membrane hyperpolarization accompanied by a decrease in input resistance. Reproduced from Koga T. and Bradley R. M. 2000. Biophysical properties and responses to neurotransmitters of petrosal and geniculate ganglion neurons innervating the tongue. J. Neurophysiol. 84, 1404–1413, used with permission from the American Physiological Society.

antagonist bicuculline. Because afferent sensory information to the rNST consists of relatively high-frequency spike trains, these short-term changes in inhibitory synaptic activity could potentially play a key role in taste processing by facilitating synaptic integration (Grabauskas, G. and Bradley, R. M., 1998).

A single tetanic stimulation results in potentiation of single stimulus shock-evoked IPSPs for a considerable time. This potentiation can last over 30 min (Figure 3). Tetanic stimulation results in activation of all postsynaptic $GABA_A$ receptors and induces long-lasting changes in the presynaptic GABAergic neuron. These long-lasting changes of the presynaptic neuron facilitate the release of GABA during single stimulus shock and, as a consequence, more postsynaptic receptors are activated during a single stimulus shock. Long-term potentiation of inhibition in the gustatory relay nucleus has the capability to profoundly alter transmission of

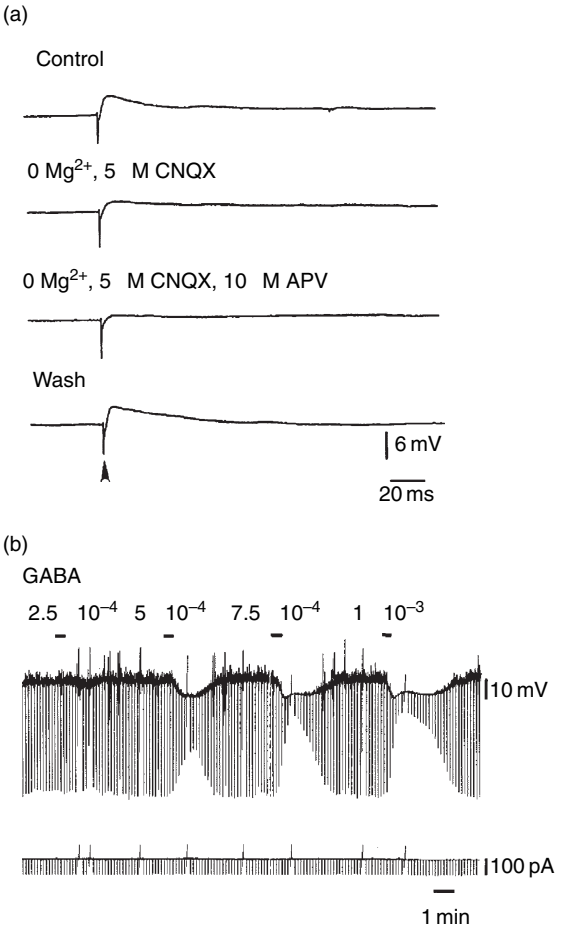

Figure 2 (a) Effect of glutamate receptor antagonists on excitatory postsynaptic potential (EPSP) recorded from a rostal nucleus of the solitary tract (rNST) neuron in a brain slice preparation superfused with physiological saline that did not contain magnesium. The EPSPs were initiated (arrowhead) by electrical stimulation of the solitary tract. Mean of 10 EPSPs under control conditions and after application of CNQX (an α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA)/kinate glutamate receptor antagonist) alone and CNQX and APV (an *N*-methyl-D-aspartate (NMDA) glutamate receptor blocker). CNQX reduced the EPSP leaving a CNQX-resistant component. The CNQX resistant component was blocked by application of APV. (b) Voltage responses recorded from an rNST neuron in a brain slice preparation to hyperpolarizing injections of −100 pA, 100 ms current pulses. The neuron was exposed to increasing 5 s (bar) concentrations of gamma-aminobutyric acid (GABA) interspersed with control saline rinses. GABA hyperpolarizes the neuron in a concentration-dependent manner accompanied by a decrease in input resistance. (a) Reproduced from Wang L. and Bradley R. M. 1995. *In vitro* study of afferent synaptic transmission in the rostral gustatory zone of the rat nucleus of the solitary tract. Brain Res. 702, 188–198, with permission from Elsevier. (b) Reproduced from Wang L. and Bradley R. M. 1993. Influence of GABA on neurons of the gustatory zone of the rat nucleus of the solitary tract. Brain Res. 616, 144–153, with permission from Elsevier.

taste information and therefore may be of significance in the mechanism of taste-related learning phenomena (Grabauskas, G. and Bradley, R. M., 1999).

The postnatal development of inhibition in rNST has also been examined (Grabauskas, G. and Bradley, R. M., 2001). All IPSPs recorded in postnatal rats were hyperpolarizing, but the rise and decay time constants of the single stimulus shock-evoked IPSPs decreased, and the inhibition response–concentration function to the GABA antagonist bicuculline shifted to the left during development. In postnatal 0 (P0)–P14, but not older animals, the IPSPs had a bicuculline insensitive component that was sensitive to block by picrotoxin, suggesting a transient expression of $GABA_C$ receptors. These developmental changes in inhibitory synaptic activity may operate to shape synaptic activity in early development of the rat gustatory system during a time of maturation of taste preferences and aversions (Grabauskas, G. and Bradley, R. M., 2001).

Other neurotransmitters and neuropeptides have been identified in the gustatory NST including SP, enkephalin, and catecholamines (Davis, B. J. and Jang, T., 1988; Davis, B. J. and Kream, R. M., 1993; Davis, B. J. and Smith, H. M., 1999). SP immunoreactivity is found within the glossopharyngeal nerve (Cuello, A. C. and Kanazawa, I., 1978; Helke, C. J. and Hill, K. M., 1988) as well as within the rNST (Cuello, A. C. and Kanazawa, I., 1978; Jacquin, T. *et al.*, 1989). Application of SP to neurons of the rNST in an *in vitro* brain slice preparation depolarized the majority of the neurons studied (68%) in a dose-dependent manner (King, M. S. *et al.*, 1993). The excitatory effect of SP was the result of direct postsynaptic action on the neurons (King, M. S. *et al.*, 1993). Similar results were reported when SP was microinjected onto rNST neurons in an *in vivo* preparation (Davis, B. J. and Smith, D. V., 1997). In this study, SP excited 48% of the neurons and enhanced the response of the rNST neurons to stimulation of the tongue with taste stimuli. In both the *in vitro* and *in vivo* studies a small number of neurons were inhibited by SP application demonstrated by membrane hyperpolarization or suppression of taste responses, respectively. Thus, SP effectively modulates the activity of gustatory neurons in rNST.

Opioids also modulate the activity of gustatory neurons in rNST (Li, C. S. *et al.*, 2003). During extracellular recording from rNST neurons, met-enkephalin was microinjected resulting in the suppression of taste initiated responses in 24% of the recorded neurons. The opioid antagonist naltrexone effectively blocked the inhibitory effect

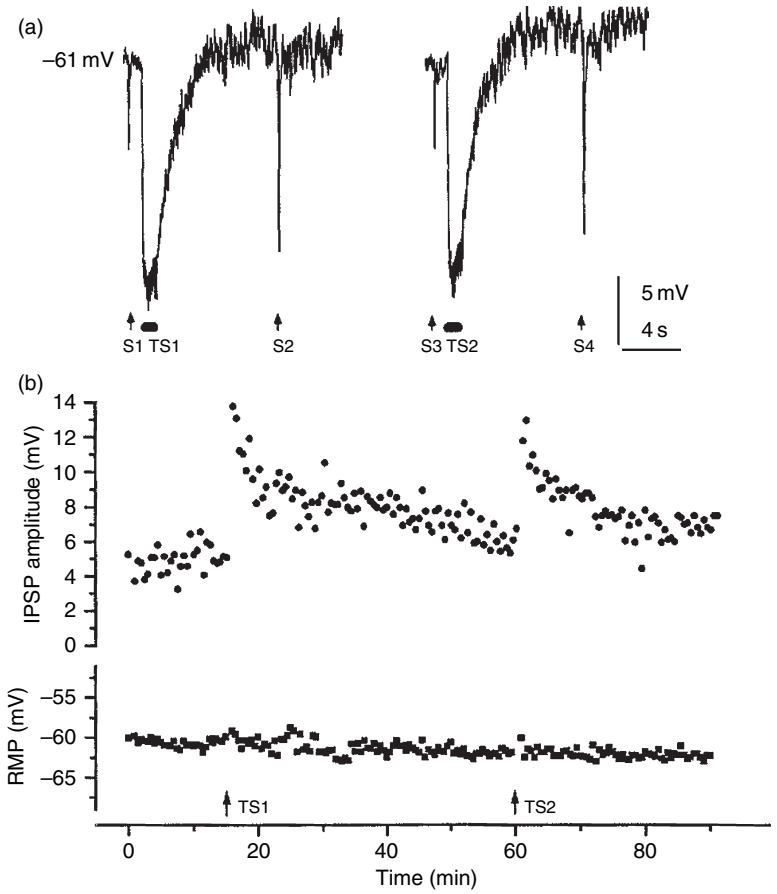

Figure 3 Effect of tetanic stimulation on inhibitory postsynaptic potentials (IPSPs) recorded from a rostal nucleus of the solitary tract (rNST) neuron in a brain slice preparation. IPSPs were isolated by chronic application of glutamate receptor blockers and elicited by electrical stimulation of the rNST. (a) After eliciting a control IPSP (S1) a tetanic stimulation (TS1) evoked potentiation of the amplitude of a subsequent IPSP (S2). Forty-five minutes after the initial potentiation the IPSP returns to control levels (S3). A second tetanic stimulation (TS2) results in potentiation again (S4). (b) Tetanic stimulation (TS1) potentiates the IPSP amplitude (●) for a considerable length of time. Tetanic stimulation does not change the resting potential (■). Once the IPSP returns to control levels a second tetanic stimulation (TS2) results in potentiation again. RMP, resting membrane potential. Reproduced from Grabauskas G. and Bradley R. M. 1999. Potentiation of GABAergic synaptic transmission in the rostral nucleus of the solitary tract. Neuroscience 94, 1173–1182, with permission from Elsevier.

of met-enkephalin suggesting that opiates maintain a tonic inhibitory action on a subpopulation of taste responsive neurons in rNST.

4.12.4 Neurotransmitters in the Parabrachial Nucleus Involved in Processing of Taste Information

In rodents and lagomorphs, gustatory information processed at the brainstem level ascends and relays in the parabrachial nucleus (PBN) in the dorsal pons (Norgren, R., 1978; Travers, J. B., 1988; Whitehead, M. C., 1990). Taste-responsive PBN neurons also have descending connections to the rNST as well as to medullary motor nuclei (Karimnamazi, H. and Travers, J. B., 1998). These connections imply that the PBN plays a significant role in taste processing by transmitting information in both a rostral and caudal direction.

The PBN has been dived into a number of major regions (Fulwiler, C. E. and Saper, C. B., 1984) with the central medial (CM), ventrolateral (VL), and waist area (W) being important in taste processing because these areas have been shown to receive input from the rNST and neurons in these areas respond to taste stimuli flowed over the tongue (Norgren, R. and Pfaffmann, C., 1975). Synaptic input from the rNST

to the PBN is mostly excitatory and mediated by glutamate since this neurotransmitter has been shown to be contained in a subset of rNST neurons that project to the PBN (Chamberlin, N. L. and Saper, C. B., 1995; Gill, C. F. *et al.*, 1999). Glutamate receptors have been shown to be present throughout the PBN but neurons in the W express AMPA (Chamberlin, N. L. and Saper, C. B., 1995; Guthmann, A. and Herbert, H., 1999c), NMDA receptors (Zidichouski, J. A. *et al.*, 1996; Guthman, A. and Herbert, H., 1999b) as well as metabotropic glutamate receptors (Zidichouski, J. A. *et al.*, 1996; Guthman, A. and Herbert, H., 1999a).

Investigators have also demonstrated that PBN neurons receive inhibitory input from the NST (Granata, A. R. and Kitai, S. T., 1989; Jhamandas, J. H. and Harris, K. H., 1992; Suemori, K. *et al.*, 1994). Based on the results of injections of GABA agonists and antagonists into the PBN this inhibition has been demonstrated to be GABAergic (Christie, M. J. and North, R. A., 1988; Mollace, V. *et al.*, 1991). The effect of GABA was studied on gustatory PBN neurons *in vitro* indicating that GABA functions as an inhibitory neurotransmitter in the gustatory PBN, mediated principally by $GABA_A$ receptors (Kobashi, M. and Bradley, R. M., 1998). At present no specific information is available on other neurotransmitters active on neurons in the gustatory PBN or on other synaptic relays in the ascending gustatory pathway.

4.12.5 Role of Neurotransmitters in Brainstem Taste-Initiated Reflex Activity

4.12.5.1 Gusto-Salivary Reflex Activity

Saliva is essential in the initial stages of taste transduction, acting as a solvent for taste stimuli, as a transport medium of the dissolved stimuli, and a possible source of ions that pass through taste receptor apical ion channels to depolarize or hyperpolarize the taste cell (Bradley, R. M., 1991). In concert, stimulation of taste receptors reflexly initiates saliva flow (Matsuo, R., 1999a). This reflex pathway involves afferent input to the rNST that then synapses with parasympathetic secretomotor neurons innervating the salivary glands. The parasympathetic neurons are collected in a column of brainstem neurons termed salivatory nuclei that are closely associated with the medial border of the rNST. Dendrites of the salivatory neurons penetrate into the rNST (Kim, M. *et al.*, 2004) facilitating synaptic contacts.

Recordings from identified neurons of the salivatory nuclei have demonstrated that the postsynaptic potentials initiated by stimulation of the solitary tract or adjacent neuropil are a mixture of excitation and inhibition (Mitoh, Y. *et al.*, 2004; Bradley, R. M. *et al.*, 2005). Application of synaptic agonists and antagonists have revealed that the excitatory component is mediated by NMDA and AMPA receptors and that inhibition results from stimulation of $GABA_A$ receptors (Mitoh, Y. *et al.*, 2004; Suwabe, T. and Bradley, R. M., 2005). Glycinergic receptors have been demonstrated on some salivatory neurons also (Mitoh, Y. *et al.*, 2004). Somata and dendrites of salivatory neurons receive symmetric synapses from glutamatergic, GABA, and glycine immunoreactive varicosities (Kobayashi, M. *et al.*, 1997). Salivatory nucleus neuron somata were shown to be strongly positive for the glutamate receptor subtypes NR1, NR2A, and either unlabeled or weakly positive for other glutamate receptor subtypes indicating that postsynaptic activity is mediated principally by NMDA receptors (Kim, M. *et al.*, 2005; Figure 4). Based on the neurophysiological measures these excitatory and inhibitory synapses are either monosynaptic connections between primary afferent fibers or involve polysynaptic connections via neurons in the rNST (Suwabe, T. and Bradley, R. M., 2005).

The salivary reflex is also influenced by descending input from higher brain centers (Matsuo, R., 1999b) and a number of neuropeptides have been hypothesized to be involved in this descending modulation of secretion as demonstrated by strong immunoreactivity for SP, serotonin, neuropeptide Y, somatostatin, tyrosine hydroxylase, vasoactive intestinal peptide, and calcitonin gene-related peptide (Nemoto, T. *et al.*, 1995). Of these neuropeptides, SP and serotonin have been shown to excite salivatory neurons in a concentration-dependent manner (Suwabe, T. and Bradley, R. M., 2007).

4.12.5.2 Synaptic Effects of Neuromodulators Known to have Profound Effects on Feeding Behavior on rNST Neurons

Injection of the benzodiazepine (BZ) receptor agonist diazepam into the fourth ventricle enhances food palatability and intake (Berridge, K. C. and Peciña, S., 1995), and it has been hypothesized that this phenomenon results from the action of diazepam on rNST neurons. BZs facilitate GABA-induced IPSPs

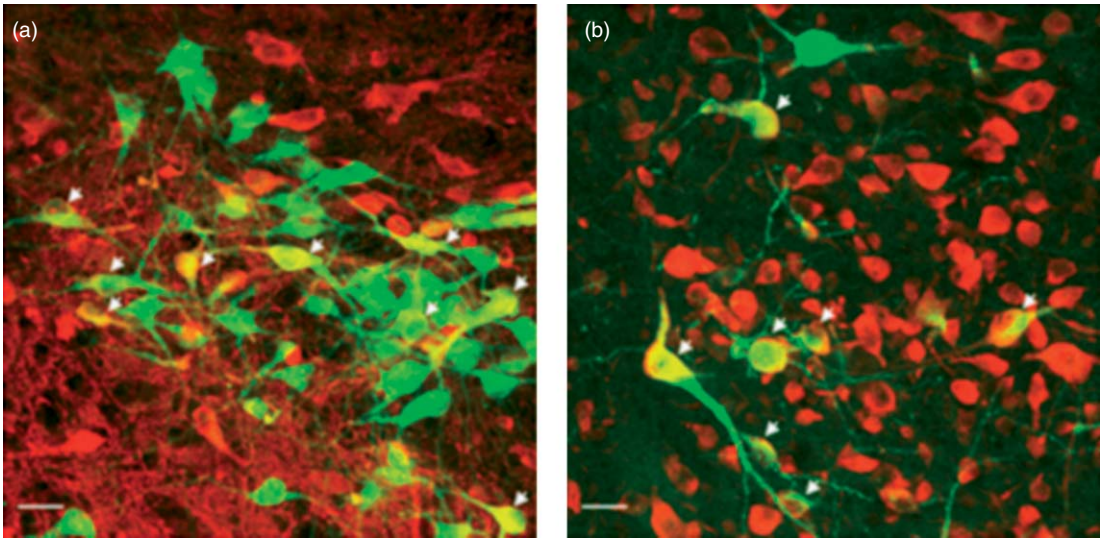

Figure 4 Glutamate receptor immunoreactivity of identified neurons of the salivatory nucleus. Parasympathetic secretomotor neurons of the inferior salivatory nucleus were identified by retrograde transport of a fluorescent marker. Horizontal sections of the medulla were subsequently immunoreacted for glutamate receptor subunits tagged with a fluorescent label. The resulting sections were examined using confocal microscopy. (a) Brainstem neurons labeled with antibodies to NR1 receptors (red) and retrogradely labeled neurons of the inferior salivatory nucleus (green). Doubled labels neurons appear yellow and are indicated by white arrows. (b) Brainstem neurons labeled with antibodies to NR2A receptors (red) and retrogradely labeled neurons of the inferior salivatory nucleus (green). Doubled labels neurons appear yellow and are indicated by white arrows. Note that many neurons in the brainstem are strongly labeled with the receptor antibody, but not all the salivatory neurons express the glutamate receptor. Scale bar = 25 μm.

in postsynaptic neurons that have $GABA_A$ receptors by modulating chloride channel activity. In brain slices maintained at body temperature, pharmacologically isolated IPSPs are diazepam sensitive demonstrating that rNST neurons express $GABA_A$ receptors with BZ binding sites. It is possible, therefore, that application of BZ into the fourth ventricle influences food intake by potentiation of GABAergic neurotransmission in the rNST (Grabauskas, G. and Bradley, R. M., 2000).

Cholecystokinin (CCK), a peptide secreted by gastrointestinal tract-lining cells, plays an important role in digestion. CCK has also been shown to cause satiety by acting centrally (Baile, C. A. *et al.*, 1986) and neurons immunoreactive for CCK have been located in the NST (Kubota, Y. *et al.*, 1983) and the PBN, including the W (Kubota, Y. *et al.*, 1983; Block, C. H. and Hoffman, G., 1987; Sutin, E. L. and Jacobowitz, D. M., 1988; Herbert, H. and Saper, C. B., 1990; Födor, M. *et al.*, 1992). Thus, CCK is present in the NST and taste-responsive area of the PBN suggesting that this neuropeptide may have a role in taste processing. While investigators using electrophysiological methods have demonstrated that CCK can modulate the excitatory response initiated by vagal stimulation (Saleh, T. M. and Cechetto, D. F., 1996) there are no similar studies on taste-responsive neurons in the PBN.

4.12.6 Conclusions

The essence of neural processing involves synaptic interactions and synaptic interactions involve neurotransmitters. Investigators studying taste processing have only recently turned their attention to the role of neurotransmitters at each relay in the taste pathway. In the review by Travers J. B. *et al.* (1987) on gustatory neural processing in the hindbrain, neurotransmitters are not even mentioned. Since that time a number of investigators have demonstrated both anatomically and physiologically the role neurotransmission plays in taste processing. They have determined that glutamate is the excitatory transmitter between afferent taste fibers and neurons of the rNST. They have demonstrated that inhibition mediated principally by $GABA_A$ receptors is an important factor in modulating the afferent input and that neurons of the rNST are under tonic GABA inhibition. Moreover, a form of long-term

inhibition must also be factored into gustatory processing by rNST circuits. It is important to also remember that afferent information is distributed to a number of destinations after arriving at the brainstem and that each of these circuits may use different neurotransmitters. Other neurotransmitters are also important as well, and some of these have been characterized, particularly SP. Besides neurotransmitters active in the ascending pathway other neurotransmitters are found in the descending pathways from more rostral brain areas. While much more information remains to be acquired it is evident from the current state of knowledge that the apparent complexity of synaptic interactions at all levels of the taste pathway should be taken into account when the subject of central taste coding is discussed.

Glossary

chemotopy Similar to tonotopy or somatotopy. For taste, still an hypothesis: the different chemicals would elicit an activation in a given localization of the primary projection area in the cortex.

EGM Electrogustometry. The application of a very low current on the tongue moves the saliva cations toward the microvillosities of the taste pores; detection thresholds are easily and precisely measured varying the current.

finger span A technique for perceived intensity evaluation. The forefinger is attached to the cursor of a potentiometer, while the thumb is fixed at the end of the resistor: the distance between both finger tips, a reflect of the articulation opening, measures the perceived intensity.

fMRI Functional magnetic resonance imaging, a brain imaging technique.

MEG Magnetoencephalography, a brain imaging technique.

NMR Nuclear magnetic resonance.

TEP Tomography by emission of positrons, a brain imaging technique.

T–I Time–intensity. The perception profile is continuously measured during the stimulation or even after the stimulation has ended, during a persisting aftertaste.

4.13.1 History of Functional Magnetic Resonance Imaging Applied to the Study of Task-Dependent Cerebral Activation

Roy C. W. and Sherrington C. S. (1890) were the first to suggest that an increase of the local blood flow may signal an increased neuronal activity, which is now possibly visualized using nuclear magnetic resonance (NMR) imaging (Lauterbur, P. C., 1973). Neural activity results in an increased blood flow with a relative decrease in deoxyhemoglobin and an increase in oxyhemoglobin. Many efforts were developed to map brain tissue and brain activity (Le Bihan, D. *et al.*, 1986; Belliveau *et al.*, 1991; Kwong, K. K. *et al.*, 1992; Ogawa, S. *et al.*, 1992), leading to the first observation of

an increased oxygen content in the visual area under stimulation. Functional magnetic resonance imaging (fMRI) uses the magnetic resonance of protons in living tissues. Spins carried by molecules are labeled by gradient pulses. During the relaxation time after a first pulse, a second one is applied which will result in a net phase shift. A relative decrease in deoxyhemoglobin (blood oxygenated level-dependent effect, BOLD) is reflected as an increase in the relaxation time, hence, as an increase of the magnetic resonance signal. The signal is an indirect reflect of the neural activity. Fundamental research in fMRI imaging is still under development to record signals that should be as close as possible from the neuronal activity.

After stimulating the spins, echoes are collected to form an image of the moving spins. With single-shot brain images that typically last between 25 and 100 ms (for example in echo-planar imaging, EPI), the technique allows powerful statistics and minimizes motion artifacts, offering a high spatial resolution of 1 mm or better. New statistical developments now care for naturally different amplitudes of the signal for repeated stimuli (in event-related experiments). The most important breakthrough brought by fMRI is that averaging data across brains is not necessary as in positron emission tomography (PET), thus allowing interpretation of individual brain activity and the study of interindividual differences (functional inter-individual differences). After a brilliant start with visual, counting, finger tapping, speech and memory tasks, chemoreception was a new challenge with the difficulty of mastering stimulation from a distance. A whole body magnet puts the subject's mouth at a minimum of 1.60 m from the outside of the machine, and every apparatus including magnetic parts must be localized outside of the shielded room, some 8 m apart.

But, as for PET, the temporal resolution is limited by the timing of the physiological event actually recorded, which is not the electrical activity of neurons but the delayed hemodynamic response, between 5 and 8 s. The temporal data acquisition is *de facto* averaged with this time constant. For a better time resolution, magnetoencephalography (MEG), directly recording the brain electrical activity, is a complementary choice. Magnetic fields are measured using SQUID sensors on the whole scalp. The signal emitted by active regions of the brain is collected in each sensor, sampled, and filtered. A number of trials (30–40) are summated. The magnitude of the neuromagnetic field at each sensor is compared to a magnitude calculated at the same sensor based on a theoretical model by the Grynszpan–Geselowitz equation (Grynszpan, F. and Geselowitz, D. B., 1973). The difference observed at each sensor results from the neuronal activity, the localization of which is to be found by mathematically resolving the inverse problem. The number of activated foci responsible for the signal is arbitrarily determined by the experimenter, and their localization, at first putative, is confirmed by the minimization algorithm. The advantage of the technique is that the recorded signal is directly generated by the electrical activity of neurones with a temporal precision of 1 ms.

Associating both fMRI and MEG techniques enables researchers to look at firing foci in individual brains with the precision of 1 ms and 1 mm, provided the experimental paradigm records enough psychophysical data for the interpretation of the function of the task-activated foci. Not only similarities but also differences of results may be informative as both techniques look at physiological events through different time windows.

4.13.2 Mapping Brain Activity in Response to Taste Stimulation

The pioneering work imaging brain activation for taste was from Kinomura S. with PET in 1994 showing thalamus, insular cortex, anterior cingulate gyrus, parahippocampal gyrus, lingual gyrus, caudate nucleus, and temporal gyrus activation (Kinomura, S. *et al.*, 1994). The same year, we started experimenting with fMRI in the 3T of the Service Frédéric Joliot (CEA) at Orsay, Director D. Le Bihan. We developed a stimulating method in order to suppress somatic information, sensory adaptation, and head movements consecutive to swallowing, using a continuous flow alternating water and stimulus in an on–off paradigm (Cerf, B. *et al.*, 1996; 1998). Small bolus (100 µl) was repetitively sent to the subject's mouth, through 2 m long silicone tubes every 3 s to minimize adaptation (pulsatile stimulation). This procedure ensured a negligible increase of the volume of fluid in the mouth with respect to saliva. Subjects were allowed to swallow *ad libitum*; hence no mouth movement could be correlated with the stimulation paradigm. The time–intensity (T–I) perception profile, which was recorded with the finger-span technique using a linear potentiometer, was used as a template to correlate to the NMR signal of each pixel or voxel. This template allowed visualizing more numerous activated clusters of pixels (+400%) than the convolution (Bandettini, P. A., *et al.*, 1993) of the stimulation paradigm waveform with a standard 6 s time-constant filter. For example, the correlation between the NMR

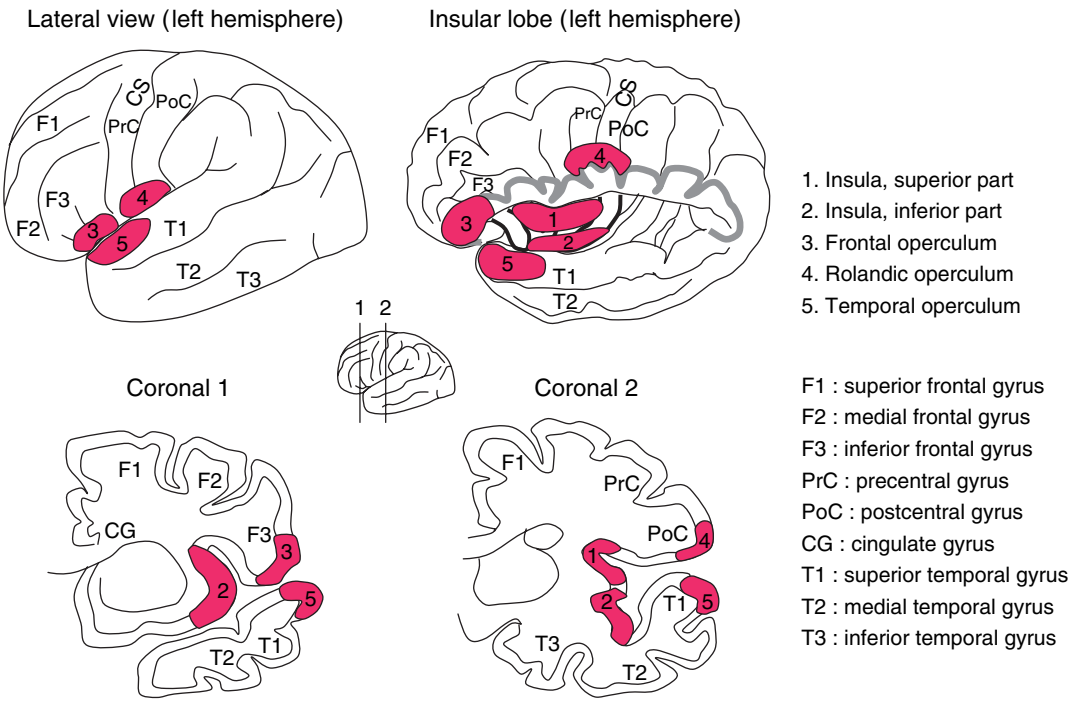

Figure 1 Brain areas activated by taste stimuli, observed with fMRI in human subjects. From Cerf, B. 1998. Doctoral dissertation, Paris.

signal and the T–I perception profile was above 0.6 in 30% of cases (thresholded at 0.4) and above 0.7 in 10% of cases instead of below 0.6 in standard conditions (Cerf, B. *et al.*, 1996; Van de Moortele, P.-F. *et al.*, 1997). The explanation comes from the waveform of recorded profiles which confirmed a slow rate of rise of the taste perception in these conditions (usually above 6 s time constant), which could vary with the stimulus and also with the subject who however individually exhibited a high reproducibility across sessions. Introducing the T–I perception measurement in the magnet enabled finding out pure taste activation that was barely detected otherwise (so-called taste is usually associated with somatosensory and retro-olfactory converging information). Hence, associating quantitative psychophysical evaluation to functional brain imaging is an important factor of success and an important factor for interpreting results. Besides, it provides a control of the stimulation. This recording of perception could also be run off-line, out of the magnet, for control sessions.

Using these conditions, and single subject analysis rather than group analysis, taste areas were localized (Figure 1) in various parts of the insula and in frontal, temporal, rolandic opercula, including pre- and postcentral gyri (Cerf, B. *et al.*, 1998; Faurion, A. *et al.*, 1999; Cerf-Ducastel, B. *et al.*, 2001) as expected from electrophysiological recordings in the monkey (Ruch, T. C. and Patton, H. D., 1946; Bagshaw, M. H. and Pribram, K. H., 1953; Benjamin, R. M. and Burton, H., 1968; Ogawa, H. *et al.*, 1985; Pritchard, T. C. *et al.*, 1986; Yaxley, S. *et al.*, 1990; Scott, T. R. *et al.*, 1991; Ogawa, H., 1994; Kadohisa, M. *et al.*, 2005) or clinical observations in humans (Bornstein, W. S., 1940; Lewey, F. H., 1943; Penfield, W. and Faulk, M. E., 1955; Motta, T. A., 1959; Hausser-Hauw, C. and Bancaud, J., 1987). Other localizations of activation of lower occurrence were not all mentioned at that time. More interestingly, a bilateral projection was found at the superior part of insula, whereas a small location in the anterior inferior insular area was found activated in the left hemisphere for strict right-handers and in the right hemisphere for left-handers (Faurion, A. *et al.*, 1999).

4.13.3 The Insular/Opercular Area and the Role of Anterior Inferior Insula

The activations due to pure taste and somatosensory or trigeminal oral stimuli, such as strong acid or potassium aluminate, were studied comparatively in the same subjects and experimental sessions. They were shown to appear in the same regions of the brain

of 12 right-handed subjects (Cerf-Ducastel, B. *et al.*, 2001). However, it was possible to make out both senses on the basis of the coactivation of areas across experiments, such as the rolandic operculum for somatosensory stimuli and the anterior inferior insula for taste. Factor analysis of the table of activated brain areas across experiments showed that the right and left rolandic operculum were discriminated from all other regions when experiments included somatosensory stimuli, whereas the right and left anterior inferior insula were discriminated from all other regions when experiments included only pure taste. It appears that multidimensional analysis sorted out the somatosensory projection area for the tongue for strong acid and astringent stimuli as an internal control of the experiment and, on the contrary, the anterior inferior insula appeared taste specific. For taste stimuli, the anterior inferior insular area was not only found again activated in the left hemisphere for right-handers but also statistically coactivated with the left angular gyrus (Cerf-Ducastel, B. *et al.*, 2001), a structure that is known to be related to comprehension of language in the dominant hemisphere of these right-handers. Furthermore, it was shown with MEG (Kobayakawa, T. *et al.*, in preparation) that this very region was the latest one to be activated, between 800 and 1400 ms for saccharin, after all other regions and after the most prominent brain activation had been recorded between 200 and 500 ms. This set of results suggests an integrative function for the inferior insula with special functions related to semantics for taste in the dominant hemisphere of right-handers, and an initial activation in the bilateral upper part of insula. A controversy remains concerning the first location of activation in this upper part of the insula, either anterior for some authors or posterior for other ones. For studying initial activation, MEG is a preferred technique, *vide infra*: timing of activation.

A much clearer picture of brain activation was obtained looking at the spatiotemporal pattern of activation. The time course of brain image formation was different for experiments including NaCl and saccharin in MEG studies, as expected from electrophysiological recordings of taste nerves in rodents. Moreover, both the temporal dimension given by the apparition of different dipoles in various places successively in the brain and the movement of each dipole we can follow during a few dozens of milliseconds helped visualizing the cross-talk activity between different brain areas and within each area during the first second of stimulation. In many behavioral experiments, this period is fairly sufficient to identify the signification of the stimulus.

Using electrogustometric stimulation at low current intensities for taste which excludes tingling sensation, in right-handed subjects, Barry M. A. *et al.* (2001) could not show a simple relationship between the side of the stimulus applied and the side where the activation was found in insular and opercular areas at individual level. However, on the group analysis, they found a predominant right activation in the frontal opercular area. Finally, in this study, taste appears to project more to the right hemisphere than lingual touch. May be the group analysis averaged different results in different subjects, or a more complex data treatment is already performed prior to this projection. By comparison, and except in the inferior anterior insula, we observed an alternated right–left prevalence depending on anteriority, with equal left and right projection in the anterior insula/opercular area at $20 < y < 30$ and a more pronounced right insular activation at $0 < y < 10$ (less anterior), which may also look subject dependent. The electrogustometric (EGM) stimulation at low current is an interesting technique to confirm that actual taste and not somatosensory responses were found in this study in the postcentral gyrus: taste (saliva cations being applied iontophoretically) elicited activation at a more ventral location of the postcentral gyrus than in Pardo J. V. *et al.* (1997) where both taste and somatosensory senses were recruited. A recent clinical study tended to show a predominantly ipsilateral projection for taste and a more prominent contralateral projection for lingual touch information (Berlucchi, G. *et al.*, 2004). Taking together their results and ours, Barry *et al.*, looking more precisely at insula, which they divided into nine parts (i.e., anterior, middle, posterior x superior, central, inferior), concluded that taste-evoked activation in the superior part seems to predominate in the right-hand side, that activation in the central part appears bilateral and that activation in the inferior part is in the dominant left hemisphere of right-handers.

4.13.4 Timing of Activation: Magnetoencephalography Experiments

MEG is the best technique to locate the first temporal activation (primary taste area). Kobayakawa T. *et al.* (1996; 1999; 2005) showed an initial activation in the most posterior superior region of insula and

rolandic operculum at onset latencies below 100 ms for salt and about 120–140 ms for saccharin. A complementary argument to assess this area was the first one to be activated came from EEG simultaneously recorded (Mizoguchi, C. *et al.*, 2002). Using electrogustometric stimulation, Yamamoto C. *et al.* (2003) showed, with MEG, a more anterior insular early projection, close to frontal operculum as shown in electrophysiological studies in primates. These discrepancies might refer to different experimental conditions.

4.13.5 Intensity Coding, Absence of Chemotopy

In the insula, Small D. M. *et al.* (2003) with fMRI and Kobayakawa T. *et al.* (2005) with MEG found indication of the coding of intensity of taste. O'Doherty J. P. *et al.* (2002) and De Araujo I. E. T. *et al.* (2003) confirmed, with fMRI, the existence of unimodal neuronal activity for taste in the anterior superior insula ($y = 3$ to 14) and frontal operculum.

O'Doherty J. *et al.* (2001) looked for topography of taste quality, but they found no trace of different localization of activation for glucose and salt: neither group analysis nor single subject analysis did provide any evidence of chemical topography in either insula or opercula. This result is not unexpected and matches well with (1) the indication of great interindividual differences of quality perception by subjects: any averaging of eventually different chemotopies would fail showing different locations for different taste qualities and with (2) the existence a continuum of numerous tastes, each stimulus being coded by a different neuronal pattern of activation, which is its signature.

4.13.6 Imagination of Taste versus Perception of Taste

Kobayashi M. *et al.* (2004) showed that the left insula was activated by gustatory imagery tasks and that the middle and superior frontal gyri which are occasionally found activated in taste experiments seemed to play an important role in the generation of hallucination of taste (top-down information, evoked imagery without the stimulus) rather than in taste perception due to the stimulus (bottom-up information).

4.13.7 Learning by Familiarization

Faurion A. *et al.* (1998; 2002) showed plasticity on repetitive imaging of subjects submitted to a protocol of familiarization to novel tastes: the number of pixels significantly changed in the insular/opercular area between the first fMRI session in which the subject tasted the novel stimuli for the first time and the second fMRI session which occurred after a heavy psychophysics session in which subjects evaluated the intensity of the novel stimuli about 120 times. The number of pixels did not change any more in the third fMRI session run after 10 more psychophysics sessions. When looking for a psychophysical parameter correlated with this pixel number variation, it was shown that the group of experiments showing an increase of the pixel number was the same as the group of experiments showing an increase of the hedonic evaluation with familiarization and that the group of experiments showing a decrease of the pixel number was the same as the group of experiments showing a decrease of the hedonic evaluation with familiarization. This result pointed to some relationship in the insular/opercular area between the evolution of the number of activated pixels and the direction of the evolution of the hedonic assessment in process of familiarization to foods, a situation that frequently occurs in everyday life for taste.

4.13.8 Orbitofrontal Cortex, an Integrative Area Contributing to Hedonic Valence and Food Reward

In the literature, the orbitofrontal cortex (OFC) is thought to be the region where the reward value of the food is expressed. If they did not find chemotopy in the insula, O'Doherty J. *et al.* (2001) showed that considering subjects taken individually, the areas activated for glucose (pleasant) and for salt (slightly unpleasant) were separated and only slightly overlapping. Averaging subjects tended to blur these interindividual differences. Hence the OFC responds to affectively positive and affectively negative taste stimuli in topographically different locations.

Small D. M. *et al.* (2003) found pleasant/aversive value in the anterior part of insula extending to the OFC. Similarly, De Araujo I. E. T. *et al.* (2003) mapped three distinct functions in the continuous region extending from the far anterior insula toward

and including the orbitofrontal cortex. They looked at taste and olfactory convergence in relation with pleasantness of flavor. If unimodal neurones for taste were found in the anterior superior insula and frontal operculum, taste and olfaction seem to converge at the far anterior (inferior) insula where it joins the OFC (MNI coordinates: 45, 15, −9), in a region even more caudal than the caudal OFC (ventral forebrain) and in the nearby cingulate gyrus, which seems to respond to the mere association of both sensations. Small D. M. *et al.* (2004) proposed that the OFC together with the insula and the anterior cingulate gyrus constitute the key components of the network underlying flavor perception, which is in agreement with electrophysiological recordings: this region is known in the primate to receive olfactory input and secondary taste projection from the primary taste area.

In the lateral anterior OFC, a positive intermodality synergistic interaction appeared as the activation in this region seems to be more pronounced for the stimulation with the mixture of sucrose taste and strawberry odor (flavor) than by the sum of the activation to each stimulus separately.

In a more medial part of the anterior OFC appeared information relevant to taste and smell subjectively matching together (judgment of congruence between taste and smell). This region was also shown to respond to pleasant odors (Zald, D. H. and Pardo, J. V., 1997) and pleasant touch (Rolls, E. T. *et al.*, 2003).

Finally, a region responding to anticipation of pleasant and unpleasant taste was found only in the OFC where regions responding to expectation of reward and reward receipt were separated (O'Doherty, J. P. *et al.*, 2002), whereas other areas in striatum (putamen, nucleus accumbens) and amygdala responded to both. The OFC appears as the key structure for efficient and rapid stimulus reinforcement of an association learning between visual or olfactory stimulus and a positive or negative reinforcer such as taste or touch (Rolls, E. T., 2004).

For the sake of comparison, Cerf, Kobayakawa, and Faurion together showed a complex long-lasting integration process including semantics and taste in the dominant hemisphere in the anterior inferior insula (-45 ± 4; 7 ± 11; -3 ± 5 and 39 ± 10; 28 ± 6; -5 ± 3), a region that is nearby the frontal operculum and the caudal OFC, and this region may be the same as, or very close to, areas that were shown to be activated by taste (38; 20; −4; −32; 22; 0) in Kringelbach M. L. *et al.* (2004), by sucrose and strawberry odor (−31; 22; 0) in de Araujo I. E. T. *et al.* (2003), by glucose (−33; 17; 2) in O'Doherty J. *et al.* (2001), and unpleasant taste (−39; 27; −3) in Small D. M. *et al.* (2003).

4.13.9 Amygdala Involved in Hedonic Valence and Memorization

In amygdala, Small D. M. *et al.* (2003) found intensity of taste, as well as aversive value. O'Doherty J. *et al.* (2001) suggested that amygdala may signal as well aversive taste and affectively positive taste. Slightly different was the result of Zald D. H. *et al.* (2002) showing that the amygdala would respond preferentially to the aversive quinine and poorly to nonaversive stimulus such as sucrose. O'Doherty J. P. *et al.* (2002) showed that the OFC and not the amygdala responded to changes in pleasantness associated with eating (satiety effect). The authors propose that flavor novelty might be expressed in the amygdala on the basis of match/mismatch association of odor and flavor. These results are confirmed by Small D. M. *et al.* (2003). It could be hypothesized that in amygdala, novelty triggers some memorization mechanisms and recall memories with cultural clues. Activation for unpleasant taste may be more pronounced than for mild pleasant taste as unpleasant taste is more impressive and probably triggers more actively the memorization circuits. Zald D. H. (2003), in a very comprehensive review, points to the fact that the amplitude of pleasantness and unpleasantness for stimuli presented is usually not equivalent, a factor that may obscure the role of the amygdala with respect to positive hedonic valence stimuli. The author stresses the importance of dissociating the arousal value from the emotional value of the stimulus presented. Another interesting point for amygdala is that it seems to be activated for low-intensity subliminal stimuli which do not elicit conscious perception. Based on animal literature, a direct fast connection between thalamus and amygdala may be the source of behavioral responses related to nonperceived subliminal though emotionally relevant stimuli.

4.13.10 Other Areas

The anterior cingulate is known to be related to emotion. De Araujo I. E. and Rolls E. T. (2004) showed an activation in the anterior cingulum for

fat independent of viscosity and for glucose, suggesting a response to the hedonic positive somatosensory aspect of fat. Small D. M. *et al.* (2004) found also activation in the anterior cingulate for congruent odor taste combination, activation depending on previous experience with taste/smell combinations.

Also the precentral gyrus at various z coordinates is often activated at various z coordinates during taste stimulation; its contribution to taste the function of which in taste is still to be determined.

Other locations were found in various studies which were at first not considered as they were either seldom or not expected from previous electrophysiological studies. As their roles were not easily interpreted, they could have been taken as putative artifacts. However, they repetitively appear in recently published studies, the number of which, although still low, now significantly increases (from one in 1994 to more than 10 in 2004) (e.g., the ventral and medial part of the thalamus, the lingual gyrus in the visual area, and the cerebellum). More numerous studies might confirm the validity of these activated areas as relevant to the taste stimulus.

Finally, Kringelbach M. L. *et al.* (2004) showed that not only the anterior insula, the frontal operculum, and the caudal OFC do respond to taste, but that taste activation is also found in the dorsolateral prefrontal cortex at a rather high level ($z = 36$). This region is already known to be implicated in response selection, working memory, attention, and integration (i.e., executive control).

4.13.11 Conclusive Remarks

So far, one of the key points for interpreting images remains that the examined areas benefit from being identified by eye recognition in anatomical images, coordinates being only indicative as they can be different from one imaging technique to another one and from one subject to another one (anatomical differences). Second, different imaging techniques (PET, fMRI, or MEG) or different stimulation protocols may identify different locations responding to taste in a given area; for example, MEG studies (Kobayakawa, T. *et al.*, 1996; 1999) did not find middle insula activation and PET studies find also more posterior activation in insula (Frey, S. and Petrides, M., 1999; Small, D. M. *et al.*, 1999) than fMRI experiments do, which also show anterior superior insular activation. The different time windows of the techniques resulting in different temporal averaging might be responsible for focusing on different regions, or the tasks given to subjects were different and accounted for different responses.

Complementary studies with MEG and fMRI associating both high temporal and spatial resolutions allow observing the dynamics of activation in the brain in response to a given tastant, with dipoles flashing as questions and answers in and toward various regions alternately, a cross-talk pattern which is specific of the quality and contextual properties of the stimulus. Such results confirm (1) the specific signature of each single tastant and (2) a widespread representation of taste information across various regions of the brain. Reliable tools are now available for mapping the individual coding of taste sensation and its relevant cultural signification, for example, for thoroughly investigating innate and acquired interindividual differences in taste perception.

4.14.1 Epithelial Na^+ Channel

4.14.1.1 Epithelial Na^+ Channel Function

Sodium (Na^+) absorption across many epithelial tissues depends on the epithelial Na^+ channel (ENaC), an apical membrane integral protein. Net absorption of Na^+ from the luminal side of the tissue to the submucosal side can occur when the luminal Na^+ concentration is equal to or less than the interstitial fluid Na^+ concentration, that is, Na^+ transport across epithelial cells is overall active, that is, coupled to metabolic energy sources (Ussing, H. H. and Zerahn, K., 1951; Verrey, F. *et al.*, 2000). However, the initial influx of Na^+ from lumen to cell occurs by passive electrodiffusion down both the Na^+ concentration gradient and the apical membrane electrical potential gradient. Cell Na^+ is then actively extruded across the basolateral membrane through sodium–potassium (Na^+-K^+) pumps (Horisberger, J. D., 2004). Net Na^+ transport can be pharmacologically blocked by either adding ouabain to the basolateral side to inhibit the Na^+-K^+ pumps or with amiloride on the apical side to reduce the Na^+ conductance of ENaC (Verrey, F. *et al.*, 2000). Before the structure of ENaC was determined, the potent effect of amiloride as a Na^+-transport blocker proved to be a reliable indication of the channel's presence, hence its much cited earlier name: amiloride-sensitive epithelial Na^+ channel. Transepithelial Na^+ transport can be monitored *in vitro* in a variety of tissues as the major component of the short-circuit current (I_{sc}) across the epithelium mounted as a tissue sheet between a pair of Ussing chambers allowing solutions with ionic composition approximating extracellular fluid to bathe both apical and basolateral tissue surfaces (Ussing, H. H. and Zerahn, K., 1951). If Na^+ enters the epithelial cells exclusively through apical membrane ENaC, then amiloride or its analogs will significantly inhibit the I_{sc} (Will, P. C. *et al.*, 1985). If Na^+ is the major ion actively absorbed, as in the

case of amphibian urinary bladder, then I_{sc} will be reduced nearly to zero (Palmer, L. G. *et al.*, 1982).

Mammalian tissues, for which the presence of ENaC has either been directly demonstrated or inferred from electrophysiological, pharmacological, or immunocytochemical studies include: the distal convoluted tubule and collecting tubules of the kidney, colon, trachea, sweat and salivary glands, and dorsal lingual epithelium including taste receptor cells (Garty, H. and Palmer, L. G., 1997). The single channel biophysical properties of Na^+-transporting ion channels obtained from patch clamp recordings from rat cortical collecting tubules and the A6 cell line from *Xenopus* kidney correspond well with those of cloned ENaC expressed in *Xenopus* oocytes (Canessa, C. M. *et al.*, 1994). Based on such comparisons the consensus opinion is that the Na^+-transporting properties of most epithelia derive from ENaC. First, ion transport in epithelia and through cloned ENaC is selective for Na^+ over K^+ with a Na^+:K^+ permeability ratio in excess of 20 (Garty, H. and Palmer, L. G., 1997; Rossier, B. C. *et al.*, 2002). Epithelial and cloned ENaC demonstrate a unitary conductance of 5 pS, an open probability of 0.5, and a dissociation constant for amiloride binding of 0.1–1.0 μM (Garty, H. and Palmer, L. G., 1997). The aldosterone-responsive epithelia of the kidney and colon are critical in the control of blood volume, blood pressure, and Na^+ balance. Consequently, in humans loss-of-function mutations in ENaC result in pseudohypoaldosteronism type 1, a severe salt wasting disease, and gain-of-function mutations cause pseudoaldosteronism, a form of salt-sensitive hypertension (Rossier, B. C. *et al.*, 2002). Na^+ consumption, in which Na^+ taste plays a role, is a factor in overall Na^+ balance. All three ENaC subunits are expressed in rat taste buds (Kretz, O. *et al.*, 1999). It is perhaps not surprising, therefore, that in mammals utilizing ENaC as a Na^+-specific taste receptor, that ENaC levels in taste cells are also modulated by aldosterone (Lin, W. *et al.*, 1999). The sensory consequence of this is that the amiloride-sensitive component of the chorda tympani taste nerve response to sodium chloride (NaCl) in rats increases following aldosterone treatment (Herness, M. S., 1992).

4.14.1.2 Epithelial Na^+ Channel Structure

ENaC is an integral membrane protein composed of three subunits, designated α, β, and γ, each of which is comprised of about 650–700 amino acids (Canessa, C. M. *et al.*, 1994). Evidence suggests the native channel consists of two α, one β, and one γ subunit (Firsov, D. *et al.*, 1998; Kosari, F. *et al.*, 1998; Figure 1).

The essential Na^+-conducting properties of ENaC are found only in the α subunit. While the β and γ subunits have no intrinsic channel function, their coexpression with the α subunit enhanced its amiloride-sensitive conductance by more than 100-fold (Canessa, C. M. *et al.*, 1994). Each subunit has just two membrane-spanning domains. Both the N- and C-termini are relatively short and located on the cytoplasmic side while the extracellular domain consists of a loop, containing nearly 70% of each subunit's amino acids, connecting the membrane-spanning hydrophobic segments (Benos, D. J. and Stanton, B. A., 1999). Evidence suggests that the major amiloride binding sites in rat ENaC involve a six amino acid residue track (α-278-283, WYRFHY), within the extracellular domain of α-rENaC (Kieber-Emmons, T. *et al.*, 1995). Histidine at α-282 appears to provide an essential electropositive moiety because mutagenesis of it to negative aspartic acid resulted in a 40-fold increase in the binding dissociation constant between amiloride and ENaC, while substitution with positive arginine decreased the dissociation constant by sixfold (Lin, C. *et al.*, 1994). The extracellular domain may also bind an accessory protein that is the site of action of serine proteases. The action of channel activating protease 1 (CAP1, prostasin), an endogenous serine protease, increases the Na^+ flux through ENaC, an effect that can be reproduced with trypsin using ENaC expressed in *Xenopus* oocytes (Chraïbi, A. *et al.*, 1998) and in rat taste receptors (see Section 4.14.2.7). Deletion of the N-terminal region of each subunit eliminates channel activity suggesting that it

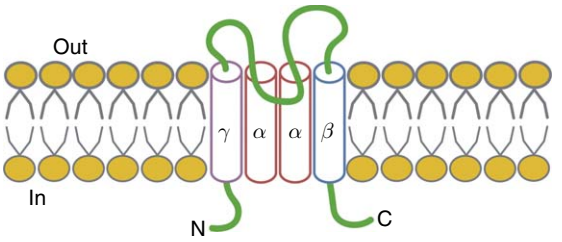

Figure 1 Model of epithelial Na^+ channel illustrating the stoichiometry among the subunits. Each subunit has two transmembrane domains (not shown) with C- and N-terminal regions in the cytoplasmic domain as shown. Reprinted, with permission, from the Annual Review of Physiology, Volume 64 © 2002 by Annual Reviews.

is important in regulating channel gating and proper assembly of functional ENaC from its subunits (Chalfant, M. L. *et al.*, 1999a). Point substitutions of serine for glycine in the N-terminus at G95 of (α-rENaC) rat ENaC, G37 of β-rENaC, or G40 of γ-rENaC significantly decrease ENaC conductance by decreasing the channel open probability (Grunder, S. *et al.*, 1997). The significance of the serine for glycine substitution at G37 of β-rENaC is evident from the fact that it is responsible for pseudohypoaldosteronism type 1. The second membrane-spanning region (M2) of each subunit and part of the pre-M1 domain contain the channel selectivity filter, sites responsible for conductance inhibition by divalent cations, and further sites involved in amiloride inhibition (Benos, D. J. and Stanton, B. A., 1999). The C-terminal region of each subunit is the most variable, and probably accounts for species and tissue differences in some of ENaC's regulatory properties, such as sensitivity to cyclic AMP (cAMP). In airway cells (Kunzelmann, K. *et al.*, 2000), renal collecting duct cells (Handler, J. S. and Orloff, J., 1981), and taste cells (Gilbertson, T. A. *et al.*, 1993; see Figure 1) cAMP stimulates amiloride-sensitive Na^+ transport through ENaC, while in mammalian colon and urinary bladder cAMP has no effect (Garty, H. and Palmer, L. G., 1997). Point mutations in a proline-rich region in the β- and γ-subunit C-termini of ENaC are sufficient to produce the gain-of-function disease, pseudoaldosteronism. This proline-rich region is important for normal internalization of ENaC from the plasma membrane and its absence results in overexpression of ENaC and a gain-of-function disease resulting in severe hypertension.

4.14.1.3 Epithelial Na^+ Channel Regulation

Salt and water balance in terrestrial mammals is tightly regulated by the hormone, aldosterone which exerts stimulatory effects on ENaC, Na^+-K^+ pumps, and various membrane ion exchangers in cells of the renal collecting duct and colon (Rossier, B. C. *et al.*, 2002). Aldosterone-sensitive Na^+ transport occurs in the duct cells of salivary and sweat glands and in the taste cells (Herness, M. S., 1992; Lin, W. *et al.*, 1999). Following a latent period of 0.5–1.0 h, the aldosterone early response, which lasts from 1.5 to 3.0 h, consists of activation of preexisting Na^+ channels and pumps. The late response (at 6–24 h) is characterized by *de novo* synthesis of ENaC and Na^+-K^+ pumps. In rat colon (Lingueglia, E. *et al.*, 1994) and rat taste cells (Lin, W. *et al.*, 1999) aldosterone increases the expression of β- and γ-ENaC without effect on α-ENaC. A second hormone, vasopressin, also increases Na^+ transport through its effects on ENaC activity. The effect is well studied in amphibian skin, urinary bladder, and amphibian-derived A6 cells (Li, J. H. Y. *et al.*, 1982). In mammals vasopressin acts on renal collecting duct cells and on taste cells (Gilbertson, T. A. *et al.*, 1993). Vasopressin binds to the membrane receptor, V_2, which in turn activates adenylyl cyclase resulting in an increased cell cAMP concentration. When cell cAMP levels are elevated pharmacologically in vasopressin-responsive epithelia, including taste cells (Gilbertson, T. A. *et al.*, 1993), the effect mimics vasopressin. cAMP increases the Na^+ conductance of epithelia by increasing the apical membrane density of ENaC without changing the channel open time probability (Morris, R. G. and Schafer, J. A., 2002). The flux of Na^+ through ENaC is observed to be locally downregulated over a range of increasing apical Na^+ concentrations, a process referred to as Na^+ self-inhibition (Lindemann, B., 1984). Na^+ self-inhibition is one of many processes by which cells resist excessive increase in osmotic pressure. This self-regulatory process has been demonstrated in rat taste cells showing amiloride sensitivity (Gilbertson, T. A. and Zhang, H., 1998). Na^+ self-inhibition can itself be inhibited by a range of compounds including: sulfhydryl reagents, organic cations, cadmium (Cd^{2+}), and zinc (Zn^{2+}). An inhibitory effect of *p*-hydroxymercuribenzoate on Na^+ self-inhibition has been shown in rat fungiform taste cells (Gilbertson, T. A. and Zhang, H., 1998). The inhibitory effect of Zn^{2+} on Na^+ self-inhibition can be demonstrated by an enhanced rat chorda tympani response to NaCl in the presence of Zn^{2+} (see Section 4.14.2.8). Intracellular calcium (Ca^{2+}) and intracellular pH exert potent regulatory effects on ENaC under physiological conditions. An increase in intracellular Ca^{2+} inhibits the Na^+ flux through ENaC (Ishikawa, T. *et al.*, 1998) as does a decrease in intracellular pH (Palmer, L. G. and Frindt, G., 1987; Chalfant, M. L. *et al.*, 1999b). These inhibitory effects of intracellular Ca^{2+} and pH can be demonstrated in the taste system in recordings of the rat chorda tympani response to NaCl (see Sections 4.14.2.3 and 4.14.2.4). In ENaC-expressing oocytes, an increase in the extracellular osmotic pressure due to nonelectrolytes such as mannitol at hyperosmotic concentrations, will also increase the Na^+ conductance of ENaC (Ji, H. L. *et al.*, 1998). This effect of hyperosmotic mannitol can be observed under

physiological conditions in recordings of the NaCl chorda tympani response (Lyall, V. *et al.*, 1999; see Section 4.14.2.5). The temperature dependence of the ENaC conductance is unusual in that it is greater at lower temperature than at higher (Chraïbi, A. and Horisberger, J. D., 2002). This appears to be due to a decrease in the channel open probability with increasing temperature. This accounts for the striking inhibition of the amiloride-sensitive part of the chorda tympani response to NaCl with increasing temperature (see Section 4.14.2.6). Proteases can eliminate the inhibitory effect of increased temperature and also can block Na^+ self-inhibition (Chraïbi, A. and Horisberger, J. D., 2002), which indicates that the temperature effect is connected with the mechanism of Na^+ self-inhibition and that proteases modulate ENaC conductance by blocking that mechanism.

4.14.2 Amiloride-Sensitive Salt Taste Receptor

4.14.2.1 Hormonal Regulation of Epithelial Na^+ Channel and Salt Taste

In rats, where ENaC plays a major role in the animal's behavior toward Na^+ salts versus non-Na^+ salts (Spector, A. C. *et al.*, 1996), data support a role for both aldosterone and vasopressin in taste cell function. Injection of Sprague-Dawley rats with aldosterone increased apical immunoreactivity to β- and γ-ENaC, increased the number of amiloride-sensitive fungiform taste cells, and enhanced the magnitude of the Na^+ current (Lin, W. *et al.*, 1999). The sensory consequence of this is that following aldosterone injection the amiloride-sensitive component of the rat chorda tympani response to NaCl was significantly increased (Herness, M. S., 1992). Vasopressin and its associated second messenger, cAMP, increased the amiloride-sensitive Na^+ current in hamster fungiform taste cells (Gilbertson, T. A. *et al.*, 1993), suggesting a role for vasopressin in taste nerve activity toward Na^+ salts. It should be emphasized that these hormonal influences are likely to be less of a factor in human salt taste because the amiloride-sensitive NaCl-taste response in humans represents the smaller component of the two salt taste-sensing mechanisms (Schiffman, S. S. *et al.*, 1983; Smith, D. V. and Ossebaard, C. A., 1995; Lyall, V. *et al.*, 2004a).

4.14.2.2 Regulation of Epithelial Na^+ Channel by cAMP and Salt Taste

While no data are available on the action of vasopressin on the chorda tympani response to NaCl, topical application of 8-(4-chlorophenylthio)-cAMP (CPT-cAMP), a membrane permeable analog of cAMP, to the rat tongue significantly enhances the response to NaCl as seen in Figure 2(a) (Russell, O. F. *et al.*, 2002). The increased response is amiloride-sensitive (data not shown) indicating that cAMP increased ENaC activity, which is consistent with its well-studied action in Na^+-transporting epithelia.

The effect of cAMP on the chorda tympani response to NaCl also suggests a possible mechanism for taste mixture interaction at the cellular level. If a subset of ENaC-containing taste cells is also responsive to tastants that modulate intracellular cAMP, it is clear that tastant-evoked modulation of cAMP can also affect cell responsiveness to NaCl as part of a stimulus mixture.

4.14.2.3 Regulation of Epithelial Na^+ Channel by Intracellular pH and Salt Taste

The decrease in the Na^+ conductance of ENaC with decreasing intracellular pH, observed in a variety of Na^+-transporting epithelia and in ENaC-expressing oocytes, also occurs in ENaC-containing taste cells (Lyall, V. *et al.*, 2002). A decrease in intracellular pH in rat taste cells decreases the Na^+ flux across the apical membranes and this pH-induced modulation of ENaC conductance in taste cells significantly affects the chorda tympani response to NaCl (Lyall, V. *et al.*, 2002; Figure 2(b)). Figure 2(b) shows the effect of extracellular pH on the neural response to 100 mM NaCl. Data show, however, that the pH regulatory site is intracellular, and that extreme extracellular pH variation (e.g., pH 2 or 10.3) produces intracellular pH changes of only a few tenths of a unit (Lyall, V. *et al.*, 2002). These changes are, however, sufficient to produce a strong effect on the Na^+ conductivity of ENaC and, therefore, account for the mixture suppression of ENaC-based salt taste by low pH and its mixture enhancement at high pH.

4.14.2.4 Regulation of Epithelial Na^+ Channel by Intracellular Ca^{2+} and Salt Taste

An increase in intracellular Ca^{2+} due to an increase in TRPM5 cation conductance occurs in taste cells during transduction for the sweet, bitter, and

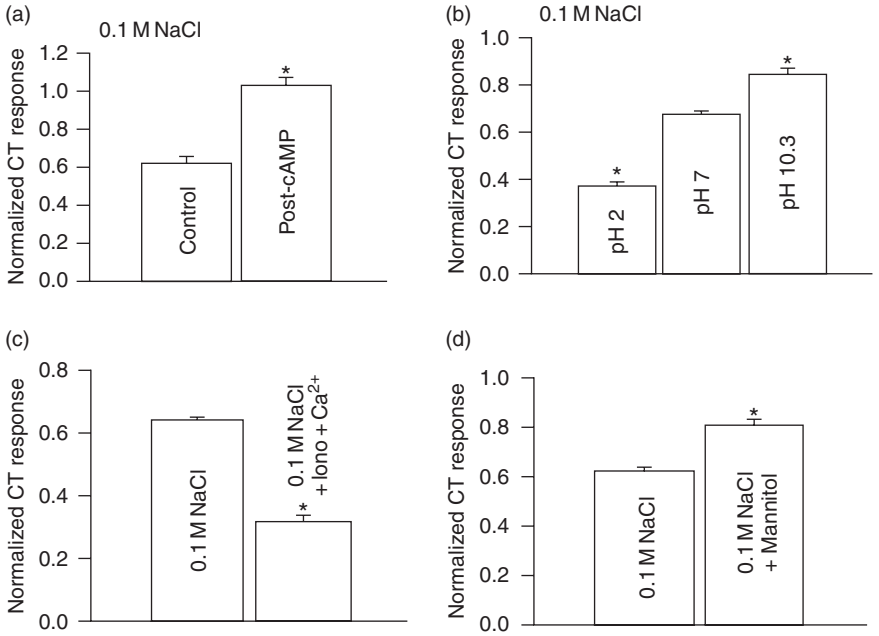

Figure 2 (a) Tonic rat chorda tympani (CT) response to 0.1 M sodium chloride (NaCl) normalized to the response to 0.3 M ammonium chloride (NH_4Cl) before (control) and following treatment of the tongue with chlorophenylthio-cAMP (CPT-cAMP) for 20 min. The increase in response due to cyclic AMP (cAMP) is consistent with an enhancement of the Na^+ flux through epithelial Na^+ channel (ENaC; cf. Russell, O. F. *et al.*, 2002). (b) Normalized CT response to 0.1 M NaCl as a function of solution pH. Results illustrate that the inhibitory effect of decreasing pH on Na^+ transport by ENaC is reflected in the neural response to NaCl (cf. Lyall, V. *et al.*, 2002). (c) Normalized CT response to 0.1 M NaCl before (control, contains 10 mM calcium chloride ($CaCl_2$)) and following treatment of the rat tongue with 150 μM ionomycin (iono) plus 10 mM $CaCl_2$. Increasing the intracellular Ca^{2+} concentration of ENaC-containing taste cells causes a decrease in the neural response to NaCl, which is consistent with the observed decrease in Na^+ conductance of ENaC due to increasing cytosolic Ca^{2+} (cf. Russell, O. F. *et al.*, 2002). (d) Normalized CT response to 0.1 M NaCl (control) and 0.1 M NaCl plus 1 M mannitol. The effect of hyperosmotic mannitol on the neural response is consistent with the observed increase in the Na^+ conductance of ENaC due to hyperosmotic mannitol. Each bar represents the mean ± standard error ($n = 3$; cf. Lyall, V. *et al.*, 1999). (b) Reproduced from The Journal of General Physiology, 2002, 120: 793–815. Copyright 2002 The Rockefeller University Press. (d) Reproduced from Lyall, V., Heck, G. L., DeSimone, J. A., and Feldman, G. M. 1999. Effects of osmolarity on taste receptor cell size and function. Am. J. Physiol. 277, C800–C813, used with permission from the American Physiological Society.

umami taste qualities (Zhang, Y. *et al.*, 2003). Sour taste also involves an increase in intracellular Ca^{2+} that both sustains transduction (Liu, L. and Simon, S. A., 2001; Richter, T. A. *et al.*, 2003) and serves as a potent stimulus for the activation of the Na^+-H^+ exchanger isoform 1, the major cellular sour taste adaptation mechanism (Lyall, V. *et al.*, 2004b; Vinnikova, A. K. *et al.*, 2004). As already discussed, ENaC conductance is reduced by an increase in intracellular Ca^{2+}. As Figure 2(c) shows, increasing taste cell intracellular Ca^{2+} using the Ca^{2+} ionophore, ionomycin, significantly suppresses the chorda tympani response to NaCl (Russell, O. F. *et al.*, 2002). Thus, any subset of cells expressing both ENaC and a second transduction or adaptation mechanism resulting in an increase in intracellular Ca^{2+}, will lead to a suppression of the cells responsiveness to NaCl.

4.14.2.5 Regulation of Epithelial Na^+ Channel by Osmolarity and Salt Taste

As mentioned above (Section 4.14.1.3), hyperosmotic mannitol increases ENaC conductance. On this basis one would expect hyperosmotic mannitol to increase the chorda tympani response to NaCl and the increased response to be abolished by amiloride significantly. This is in fact what is observed (Lyall, V. *et al.*, 1999; Figure 2(d)). Thus, ENaC-based salt taste reception is enhanced in a hyperosmotic stimulus mixture. This osmotic effect accounts for some of the taste properties in rats and hamsters of the short-chain polysaccharide, polycose. During polycose preparation low levels of salt are added which, due to the osmotic effect of the saccharide, add a detectable salt taste component to polycose solutions (Lyall, V. *et al.*, 1999). This may account, in part,

for the fact that polycose stimulates salt-sensitive units in the rat nucleus of the solitary tract and the strong behavioral preference rats show for polycose solutions (Giza, B. K. *et al.*, 1991).

4.14.2.6 Regulation of Epithelial Na^+ Channel by Temperature and Salt Taste

In oocytes expressing ENaC, the steady-state amiloride-sensitive current due to 100 mM NaCl at 36 °C was less than 50% of the current at 27 °C (Chraïbi, A. and Horisberger, J. D., 2002). This unusual inhibitory effect of increasing temperature on ENaC conductance is reflected in the amiloride-sensitive part of the chorda tympani response to NaCl. As Figure 3(c) shows the amiloride-sensitive part of the chorda tympani response to 100 mM NaCl decreased about 50% from 30.0 to 36.8 °C and rapidly decreased to zero at 43.0 °C. By contrast the amiloride-insensitive part of the NaCl response increased with temperature reaching a maximum at 43.0 °C and then declined slowly with temperature. This temperature dependence is one of many properties that indicate that the amiloride-insensitive NaCl response is mediated through a variant of the vanilloid receptor 1 (TRPV1t; Lyall, V. *et al.*, 2004a). It is clear that most of the taste sensitivity to salt at temperatures above 37 °C is not due to ENaC but rather to TRPV1t.

4.14.2.7 Regulation of Epithelial Na^+ Channel by Proteases and Salt Taste

ENaC conductance is modulated by endogenous proteases, an effect that can be mimicked using low concentrations of exogenous trypsin (Chraïbi, A. *et al.*, 1998). Trypsin, as might be anticipated, has an enhancing effect on the chorda tympani response to NaCl. As seen in Figure 3(a) the effect is specific for

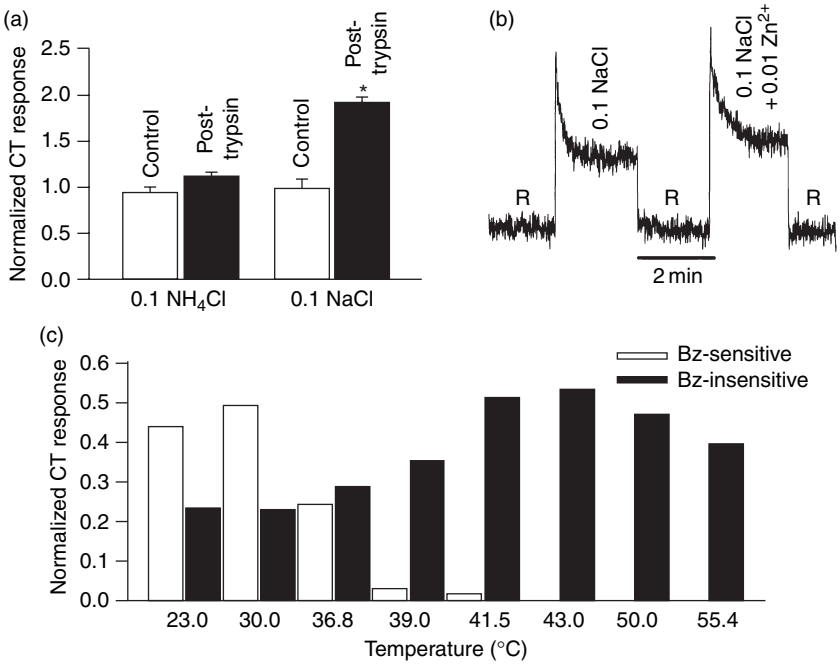

Figure 3 (a) Normalized rat chorda tympani (CT) responses to 0.1 M ammonium chloride (NH_4Cl) and 0.1 M sodium chloride (NaCl). For each salt white bars indicate control responses and black bars indicate responses following treatment of the rat tongue with 20 $\mu g\,ml^{-1}$ trypsin for 20 min. Note trypsin had no effect on the response to NH_4Cl, but increased the tonic response to NaCl by 100%. This is consistent with the observed enhancing effect of trypsin and other proteases on the Na^+ conductance of epithelial Na^+ channel (ENaC). Each bar represents the mean ± standard error ($n = 3$). (b) Chorda tympani response to 30 mM NaCl relative to a baseline response in 10 mM potassium chloride (KCl) followed by a response to 30 mM NaCl plus 10 mM zinc chloride ($ZnCl_2$). The 10 mM $ZnCl_2$ does not give a neural response above baseline. The increase in the response to NaCl by Zn^{2+} is consistent with the observed inhibitory action of Zn^{2+} on the Na^+ self-inhibition property of ENaC. (c) The amiloride-sensitive component of the chorda tympani response to 0.1 M NaCl (white bars) and the amiloride-insensitive component (black bars) as a function of temperature. Note that the amiloride-sensitive component rapidly diminishes above 30 °C, a property consistent with the observed temperature dependence of ENaC. In contrast the amiloride-insensitive component increases with temperature to a maximum at 43 °C and then slowly diminishes with increasing temperature.

responses to NaCl which is consistent with a mechanism involving ENaC and protease blockage of Na^+ self-inhibition.

4.14.2.8 Na^+ Self-Inhibition of Epithelial Na^+ Channel and Salt Taste

A wide variety of substances interfere with Na^+ self-inhibition of ENaC. Zn^{2+} concentrations too low to give a chorda tympani response in the rat, can nonetheless significantly enhance the response to NaCl. Figure 3(b) shows the chorda tympani response to 30 mM NaCl relative to a baseline in 10 mM KCl. A subsequent stimulation with 30 mM NaCl plus 10 mM $ZnCl_2$ shows a significantly enhanced response. This is consistent with Zn^{2+}-induced blockage of Na^+ self-inhibition that is in turn consistent with the effect of temperature and trypsin shown in Figures 3(c) and 3(a), respectively.

4.14.3 Summary and Conclusions

The demonstration of ENaC in rat fungiform taste receptor cells, the close conformity of the rat amiloride-sensitive neural response to NaCl, and the properties of ENaC expressed in oocytes, and the results of rat salt taste behavioral studies leave no doubt that ENaC is the Na^+-specific salt taste receptor located in the anterior tongue. All three ENaC subunits are found in fungiform taste cells in the anterior tongue, but only α-ENaC is found in abundance in the circumvallate taste cells of the posterior tongue. This may explain why amiloride sensitivity is found in the chorda tympani response to NaCl (anterior tongue), but not in the glossopharyngeal nerve response (posterior tongue) (Kretz, O. *et al.*, 1999). It should be noted, however, that treatment of rats with aldosterone induced an amiloride-sensitive Na^+ current in cells of the circumvallate papillae that normally do not have amiloride sensitivity (Lin, W. *et al.*, 1999). This suggests that perhaps aldosterone increases the targeting of ENaC subunits to the apical membrane of taste cells. A definitive answer requires, however, the cloning of each ENaC subunit from both fungiform and circumvallate taste receptor cells, a task not yet completed. Until that is accomplished it remains unclear whether the ENaC subunits in taste cells share 100% homology with complementary subunits in colon or kidney collecting tubules. While ENaC is a major salt taste receptor in rodents and other mammals, it is much less important in humans. For that reason the amiloride-insensitive salt taste receptor is beginning to receive more attention especially now that some progress has been made in its characterization (Lyall, V. *et al.*, 2004a).

4.15.1 Introduction

The sense of taste has a critical role throughout the animal kingdom because it detects and discriminates key chemicals in the animal and plant matter, which constitutes potential foodstuff. Diet varies among species and the gustatory systems of different animals exhibit important specializations. Nevertheless, mammalian species, the topic of the present chapter, possess the ubiquitous ability to sense nutritive carbohydrates and amino acids, as well as electrolytes such as sodium. Similarly, mammals distinguish potential corrosive or toxic substances including acids and alkyloids. These different groups of stimuli are described by human subjects as having distinctive qualities: most carbohydrates are sweet, acids are sour, alkaloids and other toxins are bitter, and sodium is salty; other electrolytes have mixed tastes. Amino acid taste is less well understood, but in humans, L-glutamate seems to have a special potency for activating a selective amino acid receptor (Li, X. *et al.*, 2002b) and is often assumed to have a unique taste, best known as umami. In rodents, a larger variety of L-amino acids appear to share a common transduction mechanism (Nelson, G. *et al.*, 2002), though at least glutamate is probably closely aligned perceputally with carbohydrates (Yamamoto, T. *et al.*, 1991; Stapleton, J. R. *et al.*, 1999).

Making distinctions between tastants is vital for maintaining a diet that promotes homeostasis and avoids harmful substances. The structure and function of the G-protein-coupled receptors and ion channels with the requisite specificity for this discrimination have been described in elegant detail in the last decade (reviewed in Chandrashekar, J. *et al.*, 2006). Agreement is mounting that these receptors are distributed in a relatively segregated manner (Nelson, G. *et al.*, 2001; Huang, A. L. *et al.*, 2006), such that different taste receptor cells are specialized for detecting particular classes of chemicals (Yoshida, R. *et al.*, 2006). Similarly, a notable degree of specificity is maintained

†Deceased

in the individual gustatory nerve fibers that innervate taste receptor cells, and carry this information into the brain (e.g., Frank, M., 1973; Frank, M. E. *et al.*, 1983; Frank, M. E., 1991). Thus, much of the peripheral code for taste quality is arguably sparse with just a few different groups of receptor cells and their innervating fibers comprising labeled lines. However, there is not unanimous agreement on this coding scheme, and there are important caveats particularly with regard to the code for sodium versus acids, as many peripheral nerve fibers are broadly responsive across these classes of chemicals (e.g., Frank, M., 1973; Frank, M. E. *et al.*, 1983; Frank, M. E., 1991, #241). Further, in the central nervous system, convergence of primary afferents (Ogawa, H. *et al.*, 1982; Travers, S. P. *et al.*, 1986; Sweazey, R. D. and Smith, D. V., 1987; Vogt, M. B. and Mistretta, C. M., 1990) and complex integrative processing within central circuits, gives rise to neurons with heterogeneous tuning curves, and although some neurons remain narrowly tuned (e.g., Nishijo, H. and Norgren, R., 1990; Geran, L. C. and Travers, S. P., 2006); many are broad (e.g., Nishijo, H. and Norgren, R., 1990; Di Lorenzo, P. M. and Victor, J. D., 2003; Lemon, C. H. and Smith, D. V., 2005; Geran, L. C. and Travers, S. P., 2006), as summarized in Spector A. C. and Travers S. P. (2005). As a consequence, whether any aspect of central coding employs dedicated pathways, or whether central coding relies entirely upon comparison across neurons is still a topic of considerable debate (see Chapter A Perspective on Chemosensory Quality Coding). Furthermore, there is growing interest in the possibility of a contribution of temporal coding to making distinctions among tastes (see Chapter Neural Ensembles in Taste Coding).

Overlaid on any scheme for taste quality coding are additional, equally important aspects of gustatory processing. Foods possess not only taste, but also texture, thermal, and olfactory components. These multiple characteristics are integrated largely through central circuits to produce flavor. In addition, though some taste preferences and aversions are innate, they are not hardwired. The central nervous system plays a key role in providing the requisite plasticity to meet changing homeostatic states and environmental demands. Thus, the desirability of even the most delectable dessert is suppressed by satiety. Limited specific mechanisms appear to be present to accommodate particular changes in homeostatic state. Satiety has a more pronounced impact on palatable, for example, sweet substances (Foster, L. A. *et al.*, 1996), and a sodium deficit leads to an increased preference for this specific ion (Contreras, R. and Hatton, G., 1975). However, deficits in other micro- or macronutrients, for example, vitamins or essential amino acids, are not associated with such predetermined changes in gustatory responsiveness. Instead, organisms learn to associate the flavor of a particular food with the correction of a deficit (Markison, S. *et al.*, 1999; 2000). Learning is also essential to assure that an animal will avoid contaminated food sources that do not have an innately aversive taste (Garcia, J. *et al.*, 1970).

This chapter presents data on the functional characteristics of central gustatory neurons. We consider the topographic organization of the system, as well as several key features of neurons including their tuning curves, receptive field organization, and inputs from other modalities. In addition, the plasticity of these circuits as evidenced by the impact of homeostatic state, learning, neurotransmitters and neuromodulators, and interactions between different regions of the gustatory neuraxis, is discussed. The study of the cellular basis of these features had lagged behind a systems level analysis; but significant information is now available at the level of the first-order relay, the rostral nucleus of the solitary tract (rNST). Some key ideas regarding taste quality coding are presented in the subsections following the current chapter. For a fuller perspective, the reader is referred to several recent reviews that present divergent opinions (Spector, A. C. and Travers, S. P., 2005; Chandrashekar, J. *et al.*, 2006; Jones, L. M. *et al.*, 2006; Simon, S. A. *et al.*, 2006; Hallock, R. M. and Di Lorenzo, P. M., 2006).

A schematic diagram of gustatory system organization highlighting those regions and connections discussed in this review is presented in Figure 1. Further details regarding anatomical organization can be found in the chapter in this volume by Whitehead and Finger. Classic decerebration studies by Grill H. J. and Norgren R. (1978b) established important hierarchical features of the system. When transections are made just rostral to the midbrain, the existing brainstem circuitry still possesses impressive regulatory capacity. Decerebrate rats do not voluntarily eat or drink but if fluids are introduced into their mouths, stereotyped oral behaviors, virtually identical to those observed in intact animals, assure that sweet substances are ingested and that bitter substances are rejected. Similar behaviors are observed in anencephalic human infants, establishing phylogenetic generality (Steiner, J. E., 1973). Moreover, this restricted component of the system possesses some degree of modifiability by homeostatic state, as filling the stomach with liquid food shortens bouts of licking

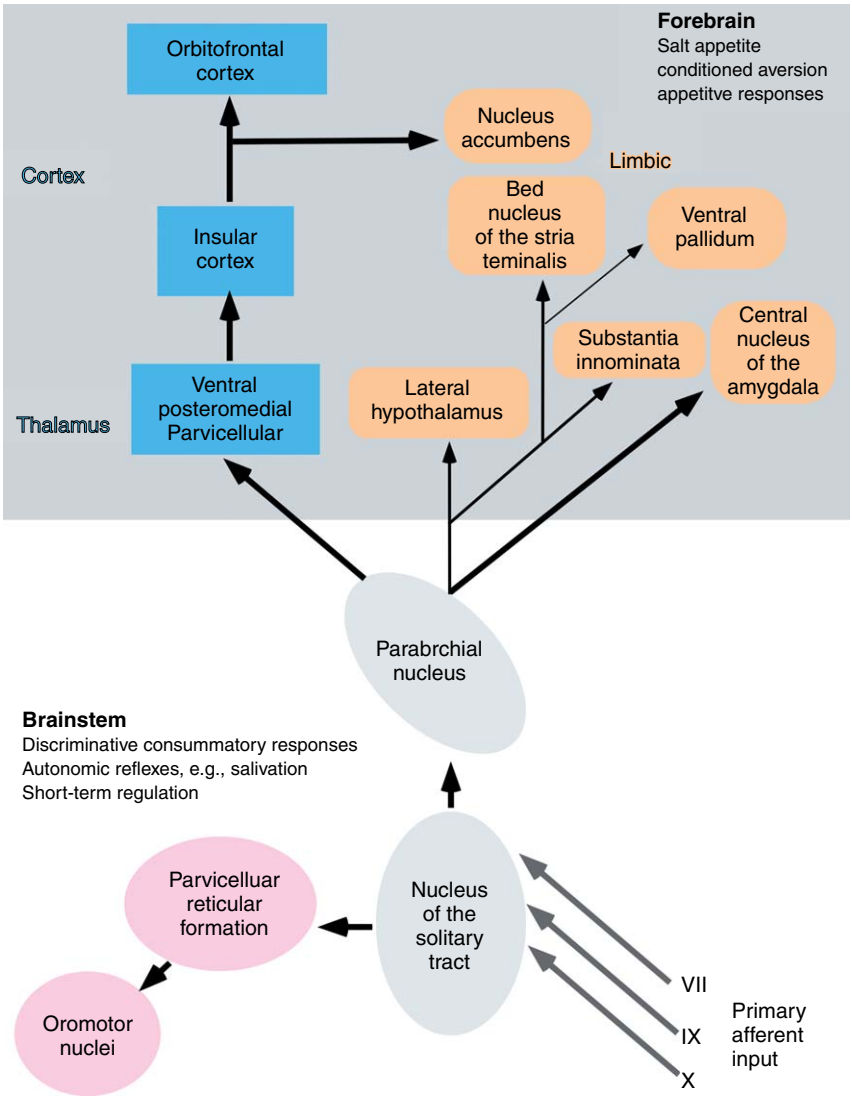

Figure 1 Schematic diagram depicting primary afferent input, and the major, direct connections of the gustatory system in rodents. Line thickness gives a rough indication of the strength of a given connection. Primate gustatory pathways are similar, despite some notable differences that are discussed in the text. The diagram also indicates two main functional divisions within the system: brainstem and forebrain, with each division associated with different behavioral repertoires. Importantly, however, there are extensive reciprocal connections between the forebrain and brainstem (see Figure 2), indicating important interactions between these two major divisions. Likewise, the gustatory forebrain can be loosely divided into thalamocortical and limbic divisions, which are differentially associated with perceptual and motivational function; however, again there are extensive anatomical connections between these networks (not shown), forming a substrate for functional interactions.

elicited by intraoral infusions of sucrose, just as it does in normal rats (Grill, H. J. and Norgren, R., 1978a). However, without the forebrain, critical aspects of modifiability are lost. Thus, longer-term changes in homeostatic state, such as that induced by food (Seeley, R. J. *et al.*, 1994; Kaplan, J. M. *et al.*, 2000) or sodium (Grill, H. J. *et al.*, 1986) deprivation cause modifications in the intake of different tasting substances in the intact, but not decerebrate rat. Finally, the effects of learning are not expressed in decerebrate animals. In intact animals, when a novel taste is paired with gastrointestinal malaise, the animal subsequently rejects that taste, a phenomenon known as conditioned taste aversion (Garcia, J. *et al.*, 1970); decerebrate rats do not exhibit this switch in behavior. Although the system is arranged hierarchically, this is not to say that the components of the system operate in isolation to perform these different functions.

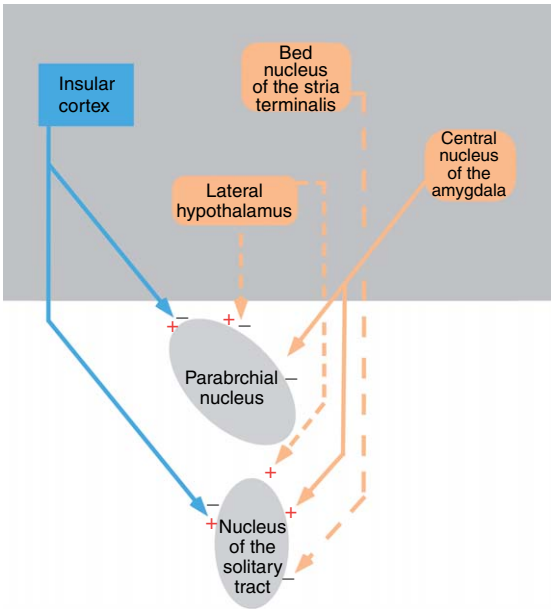

Figure 2 Major, direct, descending pathways from forebrain to brainstem, which have been documented both anatomically and physiologically. Note that all of these regions also receive ascending gustatory input, as shown in Figure 1. The most prevalent effects of electrical stimulation or glutamate activation of each forebrain structure on gustatory responses are also shown. Some effects are mixed, some largely excitatory, and others largely inhibitory.

Instead, the connections shown in Figure 2 comprise a substrate indicative of a high degree of interaction between the forebrain and hindbrain, and there are a multitude of other interactions, particularly between various regions of the forebrain.

4.15.2 Properties of Brainstem Gustatory Neurons

Taste information is processed through two brainstem nuclei on its way to the forebrain (Figure 1). Gustatory axons from the VII, IX, and X cranial nerves terminate first within the rNST, from which axons arise to project predominantly to the parabrachial nuclei (PbN) of the pons, but also to synaptic targets within the medulla, including the subadjacent reticular formation and indirectly and in some cases directly to oral motor nuclei. Cells within the nucleus of the solitary tract (NST) and PbN are also targeted by descending axons from all gustatory-responsive areas of the forebrain, providing a substrate for the modulation of taste activity in response to physiological need and prior experience. Attempts to understand the neural substrate for gustatory processing have addressed the morphology and physiology of cells within these brainstem nuclei.

4.15.2.1 Neuron Types in the Nucleus of the Solitary Tract and Parabrachial Nuclei

Progress in our understanding of many sensory or motor systems has come from a thorough description of the cells comprising the networks involved. In the gustatory brainstem, there have been numerous attempts to categorize neurons on the basis of their morphologies, intrinsic membrane properties, and taste responsiveness.

4.15.2.1.1 Morphological cell types

Neurons within the NST have been examined using a variety of anatomical techniques in an attempt to classify them on the basis of their morphologies. Purely anatomical studies have shown several prominent cell types, including multipolar (stellate), elongate (fusiform), and small ovoid cells. Several different parameters have been used to classify these cells. One of the earliest schemes grouped hamster NST cells according to their size and the invagination of their nuclei, resulting in four groups: large and small cells with or without nuclear invaginations (Davis, B. J. and Jang, T., 1986). In Nissl-stained material, Whitehead M. C. (1988) described three major cell types in the hamster NST: elongate, ovoid, and round, based on the shape of the soma, which he quantified by measuring each cell's form factor. Form factor is a measure of roundness, given by the formula $ff = 4\pi\text{area}/\text{perimeter}^2$, ranging from 1.0 for a perfectly round cell to 0.0 for a straight line. Elongate cells were those with $ff < 0.7$, ovoid with ff between 0.7 and 0.9, and round with $ff > 0.9$. Elongate cells were more common in the rostral lateral subdivision of the NST, whereas those cells within the ventral subdivision were typically larger cells. Throughout the NST, ovoid cells were the most common. Lasiter P. S. and Kachele D. L. (1988) described similar cell types in the rat NST and further demonstrated that the ovoid cells had smaller cross-sectional areas than other cell types.

Later studies used Golgi impregnation to examine cells in the hamster NST. Davis B. J. and Jang T. (1988a) described two cell types:

1. large, fusiform cells with two or three relatively unbranched primary dendrites and
2. smaller, stellate cells with more numerous and more highly branched dendrites.

Using Golgi methods (Whitehead, M. C., 1988) also described elongate and stellate cells and another class he termed tufted cells, which were large neurons with several dendrites, one of which exhibited many branches. There are some discrepancies between these studies in what constitutes large versus small or medium neurons and a thorough description of these neuronal classification studies and their limitations was provided in a later review article (Schweitzer, L. *et al.*, 1995).

Immunocytochemical studies have demonstrated that many of the small ovoid neurons express the inhibitory neurotransmitter gamma-aminobutyric acid (GABA), suggesting that these numerous cells comprise a network of inhibitory interneurons within the NST (Lasiter, P. S. and Kachele, D. L., 1988). In addition, tract-tracing experiments have demonstrated that the majority of NST neurons projecting to the PbN are elongate and stellate cells (Whitehead, M. C., 1990). Further, some of these larger neurons expressed tyrosine hydroxylase or dopamine-β-hydroxylase (Davis, B. J. and Jang, T., 1988b). Overall, the idea that there are numerous small ovoid cells serving as interneurons and elongate cells and large multipolar cells comprising the PbN projection neurons within the NST is fairly well accepted. That scheme was used by King M. S. and Bradley R. M. (1994) in their attempt to relate the biophysical properties of rat NST neurons to their morphology. These investigators grouped rat NST neurons that were labeled with biocytin during *in vitro* slice recording experiments into ovoid, elongate and multipolar cells, although they admitted that such a straightforward classification was not always easy. Nevertheless, the 58 neurons that they reconstructed were divided into 9 elongate, 21 multipolar, and 28 ovoid cells. These cell types, however, were not clearly related to the biophysical properties of the neurons (see below). A similar attempt to correlate electrophysiology and morphology was made by Renehan W. E. *et al.* (1994; 1996), who labeled rat NST cells with biocytin *in vivo* after recording their responses to gustatory stimulation. Although there was some indication that cells responding to quinine were smaller than those responding to sucrose, NaCl or HCl and that some cells had greater or lesser dendritic dimensions, there was little or no relationship between gustatory responsiveness and cell classification into elongate, multipolar, or ovoid neurons. These authors actually used a hierarchical cluster analysis to classify rat NST neurons based on their morphologies, but the resultant six classifications did not relate clearly to taste responsiveness either. Thus, cells in the NST are classifiable into groups based on morphology, as is common in many areas of the brain, but so far the functional significance of such a classification is not apparent.

4.15.2.1.2 Cell types based on biophysical properties

With the advent of brain slice techniques, it has become possible to characterize many of the intrinsic membrane properties of brainstem gustatory neurons, particularly those in the rostral portion of the NST. In pioneering work on rat medullary slices, Bradley R. M. and Sweazey R. D. (1990; 1992) demonstrated four different groups of NST neurons based on their responses to injected current (Figure 3). Three groups of cells (groups I–III) exhibited regular firing in whole-cell recordings in response to a 1200 ms, 100 pA depolarizing current injection. These groups were separable on the basis of the effects of a preceding hyperpolarization on this firing pattern produced by a 150 ms, 200 pA hyperpolarizing pulse. The firing of group I cells was severely disrupted by hyperpolarization, whereas those of group III were completely unaffected by hyperpolarizing the membrane. Group II cells showed regular firing to a depolarizing current step after an initial delay produced by the preceding hyperpolarization; this delay was produced by activation of a potassium A current (I_{KA}) (Tell, F. and Bradley, R. M., 1994) as it was this current that was blocked by 4-aminopyridine. Cells of group IV showed only a brief, rapid burst of action potentials to depolarization, which was variably affected by prior hyperpolarization. These different groups of neurons would be expected to respond differently to excitatory and inhibitory influences in the processing of gustatory information.

In a more recent study of rat NST neurons, a group of cells was identified that exhibited a depolarizing response to hyperpolarization, known as I_h current (Uteshev, V. V. and Smith, D. V., 2006). In response to hyperpolarizing current steps, these cells exhibit a nonohmic response in which the membrane potential depolarizes during the hyperpolarization, due to hyperpolarization-activated cation channels. This current is blocked by 1 mM CsCl applied to the bath. These cells were largely a different subset than those showing I_A current and were differentially distributed within the rNST. Cells with I_A current were

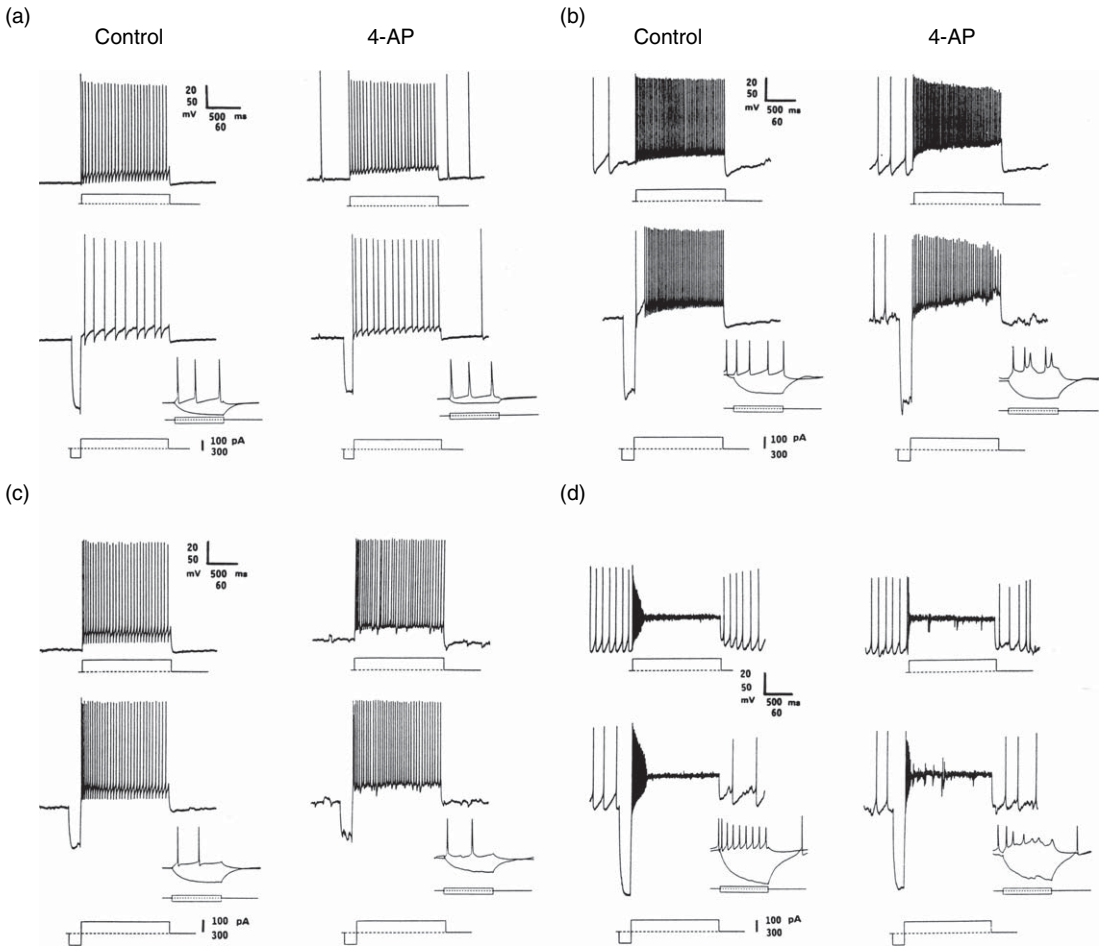

Figure 3 Types of rostral nucleus of the solitary tract (rNST) neurons defined based on membrane properties demonstrated in *in vitro* preparations. Types I–IV are shown in panels (a)–(d), respectively. Groups I–III exhibit repetitive firing throughout a depolarizing current pulse; group IV only a brief train of action potentials. Groups I–IV differ according to the effect of a preceding hyperpolarizing current pulse. Group III neurons are little affected. However, type I neurons respond with a more irregular and reduced firing and type II with a delay in the initiation of the response. Although not present in this example, a preceding hyperpolarizing pulse often shortens the burst of action potentials exhibited by type IV neurons. The response delay observed in type III neurons is eliminated by 4-aminopyridine (4-AP), indicating that a hyperpolarization elicited A-current is responsible for the delay. From Tell, F. and Bradley, R. M. 1994. Whole-cell analysis of ionic currents underlying the firing pattern of neurons in the gustatory zone of the nucleus tractus solitarii. J. Neurophysiol. 71, 479–492, with permission.

found in the medial half of the NST, where the majority of neurons projecting to the PbN are located (Halsell, C. B. *et al.*, 1996). On the other hand, those neurons expressing I_h were predominantly located in the lateral half (Uteshev, V. V. and Smith, D. V., 2006), where most of the cells project into oral motor circuits through the subadjacent reticular formation (Halsell, C. B. *et al.*, 1996). Although NST neurons can be grouped according to their responses to injected current (Bradley, R. M. and Sweazey, R. D., 1992) or by the presence of I_A or I_h current (Uteshev, V. V. and Smith, D. V., 2006), there does not appear to by any clear relationship between such classifications and cell morphology (King, M. S. and Bradley, R. M., 1994; Uteshev, V. V. and Smith, D. V., 2006).

4.15.2.1.3 Cell types based on gustatory responsiveness

A direct way to understand gustatory processing by the brainstem would be to categorize neurons on the basis of their taste responsiveness. Such an effort has

been made by almost all investigators working in this area, but the most pervasive of these classifications are the best-stimulus categories first described by Frank M. (1973) for taste-responsive fibers of the chorda tympani nerve. Chorda tympani fibers were classified into groups (S-, N-, H-, or Q-best) based on which of four basic taste stimuli: sucrose, NaCl, HCl, or quinine were most effective when presented to the anterior tongue at midrange concentrations.

A best-stimulus categorization based simply on the basis of identifying the most effective among four stimuli is subject to criticism because it is nearly a foregone conclusion that at least one stimulus will be nominally more effective than the others. However, what is more compelling is that, within a best-stimulus group, the cells are relatively similar in their overall pattern of responsiveness. Thus, when the four stimuli were ordered along the abscissa from most to least preferred (i.e., S, N, H, and Q), chorda tympani fibers peaked at a single point, with profiles indicative of S-, N-, or H-best fibers. Q-best fibers (except for one) were not evident in the hamster chorda tympani nerve, but are common in the glossopharyngeal nerve of both hamsters (Hanamori, T. *et al.*, 1988) and rats (Frank, M. E., 1991). In fact, this similarlity between members of a group holds up to the challenge of applying more stimuli and to categorizing response profiles in a more quantitative fashion; for example, by using hierarchical cluster analysis, which is a numerical taxonomic procedure (e.g., Rodieck, R. W. and Brening, R. K., 1982). When such an analysis is applied to the responses of hamster chorda tympani fibers to 13 stimuli, three groups of neurons emerge (Frank, M. E. *et al.*, 1988), which almost without exception correspond to the S-, N-, and H-best classifications. This analysis demonstrates that neurons within a group are more similar to one another than to members of other groups and provides a quantitative basis for classifying neurons in this system. In a series of experiments on the hamster brainstem, Smith and his co-workers showed that a best-stimulus classification worked well to categorize neurons of the NST (Travers, J. B. and Smith, D. V., 1979) and PbN (Van Buskirk, R. L. and Smith, D. V., 1981). Further, multivariate analyses of the response profiles of these cells, even including responses from as many as 18 stimuli, resulted in classifications that were, to a large extent, predicted from the best stimulus (Smith, D. V. *et al.*, 1983). Similar analyses of rat NST (Nakamura, K. and Norgren, R., 1993; Lemon, C. H. and Smith, D. V., 2005; Geran, L. C. and Travers, S. P., 2006) or PbN (Nishijo, H. and Norgren, R., 1990) neurons also show such neural groups, but only if taste stimuli are applied to receptors responsive to sweet stimuli. Earlier studies in rats, in which stimuli were not applied to the palate, did not present clear evidence for neural groups based on hierarchical clustering (Woolston, D. C. and Erickson, R. P., 1979) and, in fact, argued against the existence of functional neural groups. Examples from a recent study that included neurons responsive to inputs from the anterior tongue, palate, and posterior tongue are depicted in Figure 4. As a result of including neurons with inputs from the posterior foliate papillae, this study described groups of cells with optimal responses to bitter stimuli as well as to sweeteners (and amino acids), sodium, and acids. Thus, cells within the gustatory brainstem are readily classified into groups based on similarities and differences in their responses to taste stimulation.

When a classification scheme can be supported by biological parameters, it increases the confidence one places in such a categorization. An example of such support is the funneling of input from amiloride-sensitive epithelial sodium channels (ENaCs) on the taste receptor cells into a single class of neurons in the peripheral and central nervous system. Fibers of the chorda tympani nerve that respond best to NaCl exhibit responses to NaCl that are blockable in a dose-dependent fashion by lingual application of the diuretic drug amiloride (Ninomiya, Y. and Funakoshi, M., 1988; Hettinger, T. P. and Frank, M. E., 1990). The substantial response to NaCl in HCl-best fibers is much less affected by amiloride treatment. This segregation of amiloride-sensitive input to the NaCl- but not the HCl-best neurons is maintained in the NST (Scott, T. R. and Giza, B. K., 1990; Giza, B. K. and Scott, T. R., 1991). Application of amiloride to the tongue disrupts performance of rats on a two-lever operant task in which they have been taught to discriminate NaCl from KCl, implicating amiloride-sensitive NaCl-best neurons as an important contributor to the rat's ability to discriminate these two salts (Spector, A. C. *et al.*, 1996; see also Hill, D. L. *et al.*, 1990).

Another systematic relationship between chemosensitivity and a biological parameter has been described for neurons optimally responsive to bitter tasting stimuli. In a study including electrical stimulation of the PbN to test for antidromic invasion, Cho Y. K. *et al.* (2002a) found a substantial group of quinine-best neurons based on responses of the anterior tongue to equally effective concentrations of the basic stimuli: 0.032 M

sucrose, 0.032 M NaCl, 0.0032 M citric acid, and 0.032 M QHCl (quinine-HCl). When this strong concentration of QHCl is used, QHCl-best neurons are readily evident in the hamster NST following stimulation of the anterior tongue. Interestingly, all 23 QHCl-best neurons in this sample that projected axons to the PbN had conduction velocities that were less than 25% of those of the other neurons. In other words, this best-stimulus classification identified a subset of small, slowly conducting neurons. This finding corresponds well with those of Renehan W. E. *et al.* (1995) , who found that neurons responding specifically to QHCl in the rat NST were significantly smaller than other cells, and of Geran L. C. and Travers S. P. (2006) who also found that bitter-best rat NST neurons had very slow conduction velocities.

Overall, numerous studies of the responsiveness of central gustatory neurons have described groups of cells based on their best stimulus. This classification scheme corresponds well to those categories derived from more quantitative techniques such as hierarchical cluster analysis, even those based on responses to many different stimuli. To some extent, because of the relatively broader tuning of central taste neurons in comparison to peripheral gustatory fibers, the correspondence between a best-stimulus classification and a hierarchical cluster solution is not quite as tight as for peripheral fibers (Smith, D. V. *et al.*, 1983). It is also clear that changes in relative stimulus concentrations can result in changes in best-stimulus classification, as concentration–response functions for different stimuli are not always parallel (e.g., see Smith, D. V. and Travers, J. B., 1979). Nevertheless, although to some extent dependent on stimulus concentration, receptive field stimulated, and species, best-stimulus groups exhibit remarkable consistencies between laboratories and the use of such a classification scheme encompasses an important organizing principle in this system.

4.15.2.2 Neural Processing Through the Brainstem

Taste fibers traveling in the chorda tympani and greater superficial petrosal branches of the VII nerve, the lingual–tonsillar branch of the IX nerve, and the internal branch of the superior laryngeal nerve send their axons into the NST in an orderly rostral to caudal distribution (Contreras, R. J. *et al.*, 1982; Hamilton, R. B. and Norgren, R., 1984). However, the terminations of these nerves also exhibit significant overlap, giving rise to convergence between axons within the same nerve (Vogt, M. B. and Mistretta, C. M., 1990) and between inputs from completely separate receptor fields (Travers, S. P. *et al.*, 1986; Travers, S. P. and Norgren, R., 1991).

4.15.2.2.1 Breadth of tuning of nucleus of the solitary tract and parabrachial nuclei neurons

One parameter that is important in every sensory system is the tuning profile of afferent neurons. In taste, early studies described this feature by tabulating the number of stimuli among those representing the basic taste qualities that evoked activity in a recorded neuron; that is, the breadth of tuning of gustatory fibers and central neurons was simply described in terms of how many stimuli produced responses (e.g., Frank, M. and Pfaffmann, C., 1969; Perrotto, R. S. and Scott, T. R., 1976). However, such an approach depends heavily on the definition of a response, which varies across laboratories. In

Figure 4 Examples of central neuron types (rat nucleus of the solitary tract (NST)) based on chemosensitive response profiles. Types were identified using cluster analysis, and generally corresponded to a best-stimulus classification. The response types resemble those in other studies, though additional features are apparent, based on including neurons responsive to the posterior tongue, as well as including L-glutamate in the stimulus array. Two neuron types were robustly responsive to sucrose including a small group of posterior tongue responsive neurons with a relatively specific response to sucrose (S neurons), and a larger group comprised mainly of anterior oral cavity responsive neurons. The latter group also responded well to glycine, and in fact responded nominally better to glutamate (U/S neurons). Two groups responded best to sodium salts (N neurons) or acids. As is common, acid-best neurons were also robustly responsive to sodium salts, and thus named A/N neurons. Finally, there were neurons with posterior tongue receptive fields optimally and relatively specifically responsive to bitter-tasting chemicals. The multiple types of bitter-best neurons provide preliminary evidence for heterogeneous processing of different (ionic vs. nonionic) bitter tastants. SUC, 300 mM sucrose; GLY, 300 mM glycine; MSG, 30 mM monosodium glutamate + 3 mM inosine monophosphate; MPG, 30 mM monopotassium L-glutamate + 3 mM inosine monophosphate; NACL, 100 mM NaCl; NAG, 100 mM NaGluconate; HCL, 10 mM HCl; CIT, 30 mM citric acid; QUI, 3 mM quinine hydrochloride; DEN, 10 mM denatonium benzoate; PROP, 7 mM propylthiouracil; CHX, 0.01 mM cycloheximide. From Geran, L. C. and Travers, S. P. 2006. Single neurons in the nucleus of the solitary tract respond selectively to bitter taste stimuli. J. Neurophysiol. 96, 2513–2527, with permission.

1979, Smith D. V. and Travers J. B. introduced the entropy measure as a way to quantify the breadth of tuning of gustatory neurons. This measure is given by the equation:

$$H = -K \sum p_i(\log p_i), \quad i = 1, n$$

where H is the breadth of responsiveness, K is a scaling constant, and p_i is the proportional response to each of n stimuli. The p_i's for each cell are derived by converting the neural response profile for that cell to a proportional profile, the response to each stimulus being expressed as a proportion of the total response to all four stimuli. This manipulation maintains the relative response to all stimuli and does not depend upon a response criterion. Therefore, a cell might be considered broadly responsive if it responds well to its best stimulus and strongly to one other or weakly to two or three others. An $H = 1.0$ indicates a cell that is equally responsive to all four stimuli, whereas an $H = 0.0$ indicates a cell responding exclusively to one stimulus of the four. This measure has seen extensive use over the past 25 years in the study of both peripheral and central gustatory neurons (see Spector, A. C. and Travers, S. P., 2005 for a thorough review of this literature). Recently, Spector A. C. and Travers S. P. (2005) have proposed an additional measure of response tuning, which they termed the noise-to-signal measure, which takes into account the relative magnitudes of the responses to the most and second most effective stimuli. Using this approach, a cell with a large second response would be considered more broadly tuned than one with responses to all three other stimuli if their responses were smaller. Both approaches together can provide a good description of the breadth of tuning of gustatory neurons.

Comparing the breadth of tuning across levels of the gustatory system is difficult, even with a standard way of measuring response breadth. Different laboratories often use different stimuli and concentrations, and also study neurons receiving input from different regions of the mouth, all of which can impact how broadly tuned the cells appear. For example, Figure 4 depicted bitter-best neurons with relatively narrow tuning to bitter stimuli and posterior tongue receptive fields. However, another recent study, which concentrated on the anterior mouth-responsive portion of NST, and which used different concentrations of electrolytes and different bitter tastants, reported that bitter-responsive neurons responded nearly equally to salty and sour stimuli (Lemon, C. H. and Smith, D. V., 2005) (Figure 5).

To avoid such complications, a direct comparison of hamster chorda tympani, NST, and PbN responses was made using the same stimuli and concentrations. The results demonstrated that cells within the brainstem are more broadly tuned than peripheral gustatory axons (Van Buskirk, R. L. and Smith, D, V., 1981). Among chorda tympani fibers, the sucrose-best neurons are the most narrowly tuned (mean $H = 0.386$, compared to 0.587 for NaCl-best and 0.668 for HCl-best neurons). At the level of the NST, sucrose-best neurons are significantly more broadly responsive ($H = 0.586$) and this breadth increases again at the level of the PbN ($H = 0.743$). Thus, the one neuron type in the periphery which stands out for its narrow tuning becomes systematically more broadly tuned as information converges onto neurons in the medulla and pons of the hamster. In fact, at the level of the pons, sucrose-best neurons are more broadly tuned than the broadly tuned HCl-best fibers of the chorda tympani nerve. There is a wealth of data on several species and several levels of the nervous system about the breadth of responsiveness of gustatory neurons (summarized in Spector, A. C. and Travers, S. P., 2005). Overall, many cells in the central nervous system are relatively broadly responsive to stimuli representing different taste qualities; however, some neurons with more specific tuning profiles can also be observed.

4.15.2.2.2 Convergence, orotopy, and oral somatosensory responsiveness

Fibers of the chorda tympani nerve typically innervate taste cells in multiple fungiform papillae, although the sensitivities of each branch appear to be highly similar, suggesting that taste axons are guided to make connections to particular receptors (Oakley, B. *et al.*, 1979; see also Ninomiya, Y., 1998). Thus convergence of separate axonal branches within the tongue does not appreciably increase the breadth of a neuron's responsiveness. On the other hand, when recordings are made from neurons in the NST, separate receptive fields are seen to converge (Vogt, M. B. and Mistretta, C. M., 1990), resulting in greater breadth of responsiveness. Further, axons from completely separate receptor populations have been shown to converge on NST neurons in the rat (Ogawa, H. and Hayama, T., 1984), particularly between the palate and anterior tongue (Travers, S. P. *et al.*, 1986; Travers, S. P. and Norgren, R., 1991). These neurons often responded best to NaCl applied to the anterior tongue and sucrose applied to the

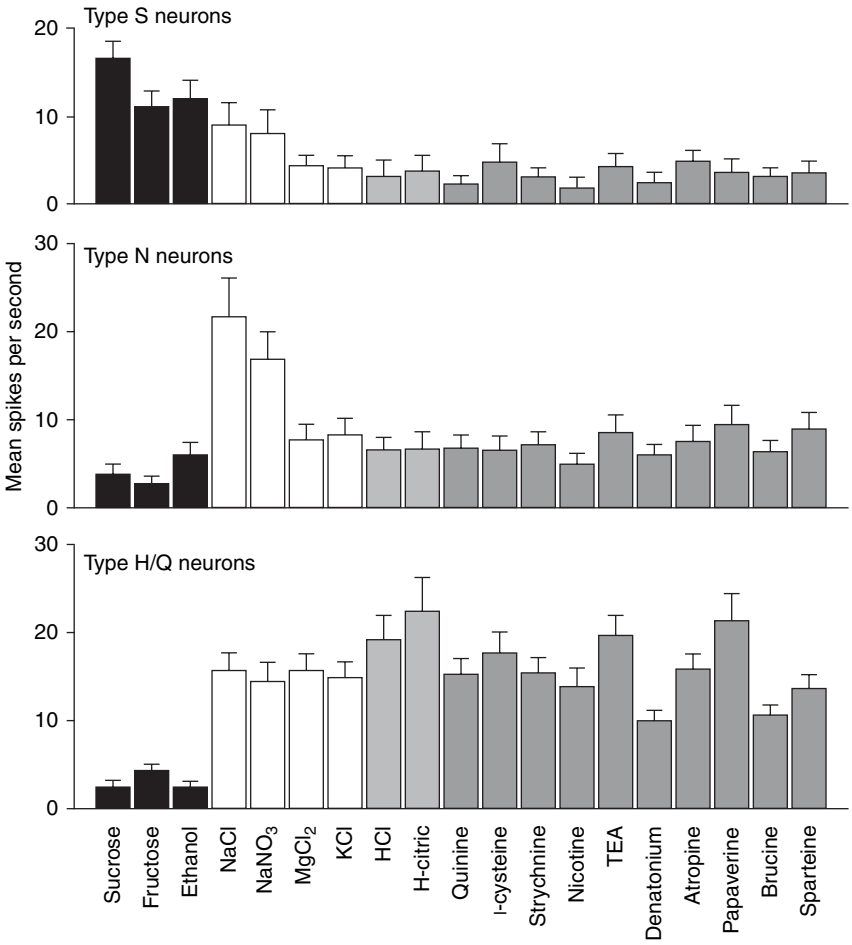

Figure 5 Further examples of rat nucleus of the solitary tract (NST) neuron types based on chemosensitive response profiles. The N neurons strongly resemble the N neurons in Figure 4, and the S neurons are similar to the S/U neurons in Figure 4. However, neurons with selective responses to bitter tastants were not apparent. Instead, neurons with optimal responses to acids responded nearly as well to salts and bitter stimuli. Stimuli: 320 mM sucrose, 500 mM fructose, 40% ethanol, 10 mM NaCl, 8 mM $NaNO_3$, 3 mM HCl, 5 mM citric acid, 10 mM $MgCl_2$, 5 mM KCl, 15 mM denatonium benzoate, 3 mM L-cysteine, 1 mM nicotine, 5 mM strychnine, 40 mM tetraethylammonium, 30 mM atropine, 5 mM brucine, 30 mM papaverine, 9 mM sparteine, 7 mM quinine hydrochloride. From Lemon, C. H. and Smith, D. V. 2005. Neural representation of bitter taste in the nucleus of the solitary tract. J. Neurophysiol. 94, 3719–3729 with permission.

palate. Convergence from different parts of the oral cavity onto cells in the hamster NST has also been described (Sweazey, R. D. and Smith, D. V., 1987). Convergence of peripheral axons onto neurons of the NST is probably responsible for the increased breadth of responsiveness seen in NST neurons over peripheral fibers. Although there are little or no data on whether sucrose-best fibers of the chorda tympani nerve exhibit amiloride-sensitive responses to NaCl, responses to NaCl in sucrose-best neurons in the NST are blocked by amiloride (Boughter, J. D., Jr. and Smith, D. V., 1998; St. John, S. J. and Smith, D. V., 2000), probably reflecting convergence between peripheral NaCl-best and sucrose-best chorda tympani axons onto cells of the NST. At the level of the PbN, in addition to an increase in the breadth of tuning of sucrose-best neurons (Van Buskirk, R. L. and Smith, D .V., 1981), there is direct evidence that inputs from the anterior and posterior oral cavity converge onto single neurons (Halsell, C. B. and Travers, S. P., 1997).

As a result of the diverse anatomical distribution of taste buds across the tongue, palate, and oropharyngeal and laryngeal epithelia and their innervation by three different cranial nerves, the central representation of gustatory input is arranged in an orotopic fashion (Contreras, R. J. *et al.*, 1982; Hamilton, R. B. and Norgren, R., 1984; Travers, S. P. and Norgren, R.,

1995). Within the medulla, afferent neurons of the VII nerve, including those within the chorda tympani and the greater superficial petrosal nerves, terminate in the most rostral pole of the NST. Overlapping this distribution but extending more caudally is the input from the IX nerve and this distribution is overlapped and extended more caudally still by afferent terminals of the gustatory axons of the X nerve. Consequently, the oral cavity is roughly represented spatially within the NST, with input from the anterior tongue and palate most rostral and that from the epiglottis most caudal within the nucleus. In rodents there are some differences in responsiveness to different stimuli across the various receptor fields, most notably a greater sensitivity to quinine and other bitter stimuli on the posterior tongue. This difference is reflected in the responsiveness of cells in different regions of the NST (Sweazey, R. D. and Smith, D. V., 1987; Geran, L. C. and Travers, S. P., 2006). In the PbN, gustatory input to the external lateral–inner subdivision is exclusively from the posterior oral cavity, whereas both posterior and anterior oral inputs are comingled in the central medial and ventral lateral subdivisions (Halsell, C. B. and Travers, S. P., 1997). In fact, orotopy is observed all the way to the cortex, where input from the VII and IX nerves is still somewhat segregated (e.g., Benjamin, R. M. and Akert, K., 1959). Thus input from the posterior and anterior oral cavities is partially segregated at all levels of the gustatory system. Functionally, gustatory information carried in the VII nerve, but not the IX, appears to be critical for taste discrimination (Spector, A. C. and Grill, H. J., 1992; Spector, A. C. *et al.*, 1997; St. John, S. J. and Spector, A. C., 1998), whereas aversive taste reactivity (e.g., gapes) depends upon IX nerve input (Travers, J. B. *et al.*, 1987; Grill, H. J. *et al.*, 1992). These data suggest that gustatory input carried by different cranial nerves may subserve somewhat different functional roles, as is seen quite clearly in fish, where the VII nerve is involved in food seeking and the IX in ingestion (Bardach, J. E. *et al.*, 1967; Atema, J., 1971). Although the degree of anatomical overlap between cranial nerve inputs in mammals makes such a relationship more difficult to discern, a similar functional dichotomy between VII and IX nerve gustatory function may exist.

In addition to processing gustatory information, the rNST also receives notable inputs from oral somatosensensory receptors. Somatosensory input arising from the anterior mouth reaches the nucleus though projections of oral divisions of the trigeminal nerve; and that from the posterior mouth through the IX nerve (Beckstead, R. M. and Norgren, R., 1979; Contreras, R. J. *et al.*, 1982; Hamilton, R. B. and Norgren, R., 1984). Neurons that are unresponsive to taste, but instead responsive to nonnociceptive mechanical stimulation of the oral mucosa are also arranged in an orderly orotopic fashion, laterally adjacent to the location of taste-responsive neurons (Travers, S. P. and Norgren, R., 1995). In addition, a number of gustatory-responsive neurons can also be activated by mechanical stimulation of the mouth, with such responses stronger and more prevalent in posterior-responsive neurons receiving inputs from the IX nerve (Travers, S. P. and Norgren, R., 1995).

4.15.2.2.3 Modulation of gustatory responsiveness

Gustatory neurons in the rodent PbN send projections to two distinct forebrain systems: thalamocortical and limbic (Figure 1). Double-labeling experiments have shown that some PbN neurons project to the ventral posterior medial nucleus, parvicellularis (VPMpc) of the thalamus, whereas others project to the central nucleus of the amygdala (CeA) (Voshart, K. and van der Kooy, D., 1981). From the VPMpc, gustatory information is transmitted to the gustatory insular cortex. PbN neurons also project to the lateral hypothalamus, bed nucleus of the stria terminalis, and the substantia innominata (Norgren, R., 1974; 1976). Although the precise route may be different (see below), taste information in the primate also reaches limbic, as well as thalamocortical forebrain sites. These various areas of the limbic forebrain pathway have been implicated in food and water regulation, sodium appetite, taste aversion learning, and the response to stress, suggesting a substrate through which taste activity interfaces with motivated behavior. Both the insular cortex and many of these limbic areas have feedback projections to the NST and PBN (Figure 2) (van der Kooy, D. *et al.*, 1984; Veening, J. G. *et al.*, 1984; Moga, M. M. *et al.*, 1990b; Halsell, C. B., 1998; Whitehead, M. C. *et al.*, 2000), providing a mechanism by which higher-level processing can impact taste responses at the initial stages of the pathway.

4.15.2.2.3.(i) Physiological alterations The first indications of a modulatory effect of the forebrain on taste activity came from studies on decerebrate rats, which demonstrated that taste responses in brainstem nuclei were changed by severing the connections with the forebrain (Hayama, T. *et al.*, 1985; Di Lorenzo, P. M., 1988; Mark, G. P. *et al.*, 1988). Further experiments

using reversible lesions of the insular cortex with procaine demonstrated both increased and decreased responding to taste stimulation in the PbN (Di Lorenzo, P.M. and Monroe, S., 1990) as well as the NST (Di Lorenzo, P. M. and Monroe, S., 1995). These data demonstrated that the responsiveness of gustatory neurons in the brainstem are not simply the result of the integration of afferent inputs, but are modifiable by descending circuits. Several kinds of experiments have illustrated that physiological and experiential factors may modulate the responsiveness of taste neurons in the brainstem; descending modulation presumably makes a key contribution to these influences, though local circuits most likely play a role as well.

4.15.2.2.3.(ii) Homeostatic mechanisms: feeding and appetite Gustatory input is critical to the initiation and control of ingestive behavior, guiding the choice of nutritive foods, and promoting the avoidance of toxic substances. A number of studies have shown that manipulations that alter an animal's state of satiety can have an influence on the responses of gustatory neurons in the brainstem. For example, hyperglycemia produced by intravenous infusion of glucose decreased responses to orally applied glucose in cells of the rat NST by an average of 43% (Giza, B. K. and Scott, T. R., 1983) Responses to NaCl and HCl were considerably less affected (20% and 16%, respectively) by blood glucose levels and those to QHCl (3%) not at all. Similarly, rats decreased their preference for glucose following an intravenous glucose load, which had no effect on their behavioral responses to quinine (Giza, B. K. and Scott, T. R., 1987). Therefore, when blood sugar levels are elevated, gustatory responses in the brain are decreased and the intake of glucose is concomitantly reduced. Intravenous infusion of other satiety factors, including insulin and pancreatic glucagon, also decreased NST multiunit responses to glucose, although cholecystokinin (CCK) had no effect on taste activity (Giza, B. K. *et al.*, 1992). Similarly, gastric distension has been shown to decrease the responsiveness of NST neurons to taste stimulation (Glenn, J. F. and Erickson, R. P., 1976). These factors, all of which can be signals contributing to satiety, appear to decrease gustatory sensitivity to nutritive taste stimuli.

It is generally believed that in the short-term regulation of feeding behavior, the sensory components of food play a dominant role (Smith, G. P., 1996). In sham-feeding experiments in which orosensory stimulation is isolated from any postingestive effects, fat infusions into the duodenum decrease food intake (e.g., Greenberg, D. *et al.*, 1990; Foster, L. A. *et al.*, 1996). Electrophysiological evidence indicates that intraduodenal infusion of lipid reversibly decreases the responsiveness of PbN taste neurons to sucrose and somewhat to NaCl, with no effect on responses to acid or quinine (Figure 6, Hajnal, A. *et al.*, 1999).

The effects were also differential for neuron type, indicating a further specialization for this modulation. Sucrose responses were most affected in sucrose-best neurons, and in particular those with the most specific responses to sucrose. These effects were rapid, beginning within 5–10 min, and reversible within about 40 min after the beginning of a 10 min lipid infusion. These data demonstrate that fat introduced into the duodenum has a specific effect on taste mechanisms, providing for decreased taste sensitivity to stimuli that signal nutritional value.

Another area in which nutritional need results in altered gustatory responsiveness is sodium appetite. Normal rats behaviorally choose to ingest NaCl at concentrations that maintain sodium homeostasis. Thus an isotonic concentration of about 0.15 M is avidly consumed, whereas lower concentrations are less preferred and higher concentrations become increasingly avoided; indeed rats can voluntarily mix NaCl and water to maintain isotonic levels of intake (Rinaman, L. *et al.*, 1993). However, when plasma sodium concentration declines, a condition known as hyponatremia, there are two mechanisms for returning sodium to normal levels. One is to conserve sodium through activation of the renin–antiotensin–aldosterone system to increase sodium resorption and the other is to increase the ingestion of sodium by creating a specific sodium appetite (see McCaughey, S. A. and Scott, T. R., 1998). Like most other mammals, rats that are made sodium deficient will exhibit a sodium appetite that is characterized by an increase in the intake of sodium salts, such as NaCl (Jalowiec, J. E. and Stricker, E. M., 1970; Contreras, R. and Hatton, G., 1975), which is ingested at concentrations that are normally behaviorally neutral or avoided. Investigation of the responsiveness of gustatory neurons following sodium deficiency demonstrates that the responsiveness to NaCl is decreased, particularly in those neurons most responsive to sodium salts (i.e., those with amiloride-sensitive input) in both peripheral chorda tympani axons (Contreras, R. J., 1977; Contreras, R. J. and Frank, M., 1979) and in neurons of the NST (Jacobs, K. M. *et al.*, 1988) and PbN (Shimura, T. *et al.*, 1997a). These results have been interpreted to

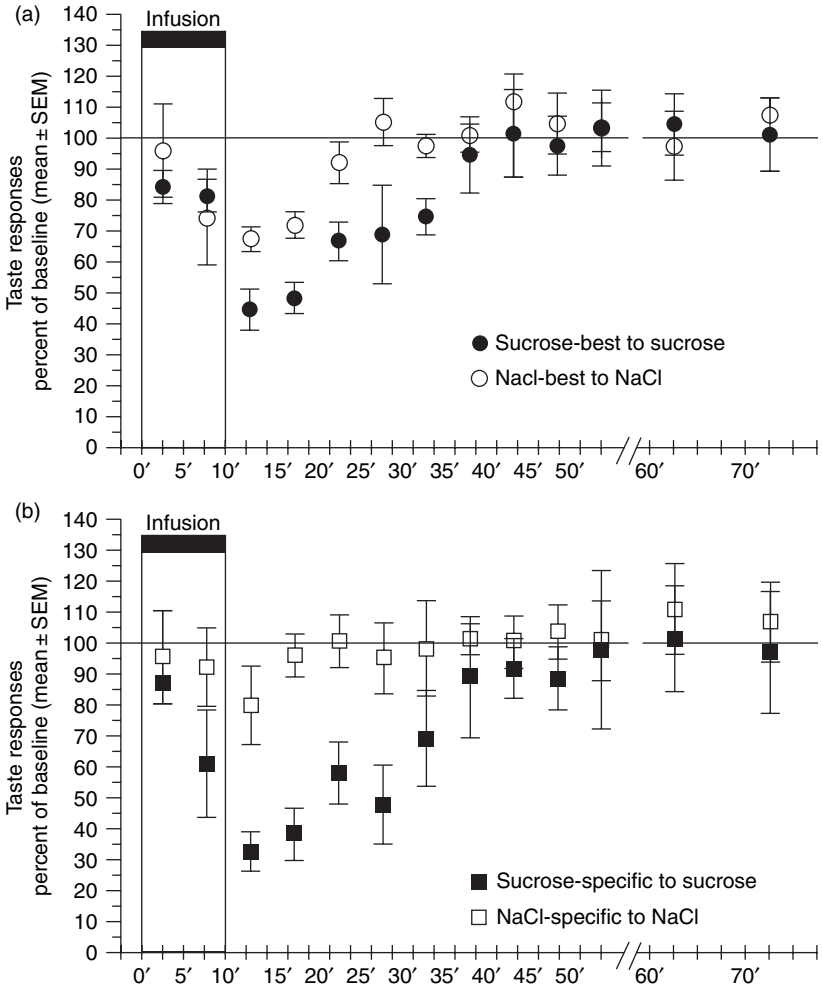

Figure 6 Effects of intraduodenal lipid infusion on taste responses in parabrachial nuclei (PbN) neurons. (a) Mean responses to sucrose in sucrose-best neurons, and mean responses to NaCl in NaCl-best neurons before and at different times after the infusion. Both the responses to sucrose and NaCl were suppressed rapidly, but the sucrose response was much more profoundly affected. (b) The sucrose effect was more pronounced in the subset of sucrose-best neurons that were most selectively tuned to this tastant; the opposite was true for the suppression of the NaCl response; lipids infusion was less effective in suppressing the NaCl response of NaCl-specific neurons. From Hajnal, A., Takenouchi, K., and Norgren, R. 1999. Effect of intraduodenal lipid on parabrachial gustatory coding in awake rats. J. Neurosci. 19, 7182–7190, with permission.

mean that a sodium-deprived rat would require greater ingestion of NaCl to establish the same level of sensory input as a normal rat (Contreras, R. J. and Frank, M., 1979). Whether or not this decrease in the sodium responsiveness is actually required for the expression of sodium appetite is unclear, however, since varying the way in which sodium appetite is induced can actually lead to opposite changes; that is, increases in brainstem taste responses (Tamura, R. and Norgren, R., 1997), even though the animal still consumes more sodium. Thus, the relationship between changes in taste responsiveness and changes in ingestive behavior do not appear simple.

4.15.2.2.3.(iii) Learning: conditioned preferences and aversions Palatable taste stimuli that are associated with gastrointestinal illness become aversive, a learning phenomenon known as conditioned taste aversion (CTA), first described by Garcia J. *et al.* (1970) . When rats are made ill following exposure to a novel stimulus, they associate the resulting illness with the taste of the stimulus and thereafter are averse to it and to other stimuli with a similar taste (Nachman, M., 1963; Halpern, B. P. and Tapper, D. N., 1971). Such behavior has survival value for the animal by helping it to avoid the ingestion of food that contains toxic substances. The generalization of CTA has been used as a

psychophysical tool to assess the similarity in quality among gustatory stimuli in experimental animal models (e.g., Smith, D. V. and Travers, J. B., 1979; Smith, D. V. *et al.*, 1979; Nowlis, G. H. *et al.*, 1980), as animals will avoid other stimuli in proportion to the perceived similarity to the conditioned stimulus (CS) (Smith, D. V. and Theodore, R. M., 1984). Several studies have shown that such conditioning alters the responsiveness of gustatory neurons, generally by making the CS a somewhat more effective stimulus. For example, Chang F. C. and Scott T. R. (1984) demonstrated that a CTA to saccharin increased the responsiveness to the CS in those neurons most responsive to sweet substances. Similarly, conditioning an aversion to NaCl resulted in an increased response to the CS in NaCl-best neurons of the rat PbN (Shimura, T. *et al.*, 1997b). Such an increase is restricted to those neurons receiving amiloride-sensitive sodium input, but this increase in responsiveness was not evident in decerebrate animals (Tokita, K. *et al.*, 2004). Thus, as shown above, sodium need leads to a decreased neural response to NaCl and increased consumption, whereas CTA leads to an increased neural response to NaCl and decreased consumption. On the other hand, when the CS was a normally nonpreferred HCl solution, the effects of CTA were the opposite: PbN responses to the CS were reduced (Shimura, T. *et al.*, 2002). When rats are conditioned to prefer a $MgCl_2$ or citric acid solution, there were slight shifts in neural responses in the rat NST, making the CS more distinct from other nonpreferred solutions, but these effects were much less robust than the effects of CTA (Giza, B. K. *et al.*, 1997).

4.15.2.2.4 Neurotransmitters and neuromodulators in the nucleus of the solitary tract

Recently, significant progress has been made in identifying the neurotransmitters and neuromodulators along the gustatory pathway, and defining their roles in gustatory information processing. In the brainstem, most is known about the NST.

4.15.2.2.4.(i) Excitatory amino acids Much of the excitatory transmission in the central nervous system is mediated by excitatory amino acids (EAAs), such as glutamate (Mayer, M. L. and Westbrook, G. L., 1987). In the visceral portions of the NST, several EAA agonists had been shown to elicit cardiovascular responses when injected into the medial NST, mimicking the effects of stimulation of baroreceptor afferent fibers, and these responses are blocked by both *N*-methyl-D-aspartic acid (NMDA) and non-NMDA antagonists (Guyenet, P. G. *et al.*, 1987; Kubo, T. and Kihara, M., 1988a; 1988b). Synaptic transmission between primary vagal afferent fibers and second-order cells of the caudal NST appears to be mediated by glutamate (Drewe, J. A. *et al.*, 1990; Glaum, S. R. *et al.*, 1992; Vardhan, A. *et al.*, 1993; Andresen, M. and Yang, M., 1994). In studies done *in vitro* on rat brainstem slices, the responses of cells in the gustatory region of the rNST to electrical stimulation of the solitary tract are reduced or blocked by antagonists of both NMDA and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainate receptors (Wang, L. and Bradley, R. M., 1995), suggesting that both NMDA and non-NMDA receptors may mediate transmission between primary gustatory fibers and second-order neurons of the NST. The direct involvement of EAA receptors in the transmission of gustatory information was shown in an *in vivo* experiment, in which gustatory responses in individual cells of the hamster NST were blocked by EAA receptor antagonists (Li, C. S. and Smith, D. V., 1997). Microinjection of kynurenic acid, a broad-spectrum EAA antagonist, into the vicinity of taste-responsive neurons of the NST completely and reversibly blocked their activity. In these *in vivo* experiments, the AMPA/kainate receptor antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) also completely and reversibly blocked these responses, although the NMDA antagonist DL-2-amino-5-phosphonovalerate (APV) was less effective. All gustatory responses in the NST were blocked by CNQX, regardless of the type of cell or nature of the gustatory stimulus (Li, C. S. and Smith, D. V., 1997). Because the *in vitro* experiments had shown colocalization of NMDA and non-NMDA receptors on many of the same NST neurons (Wang, L. and Bradley, R. M., 1995), it is likely that the NMDA receptors play a secondary role which is not easily revealed *in vivo*.

4.15.2.2.4.(ii) Gamma-aminobutyric acid, tonic inhibition There are many small ovoid neurons within the NST that express the inhibitory neurotransmitter GABA in both rats (Lasiter, P. S. and Kachele, D. L., 1988) and hamsters (Davis, B. J., 1993). Slice experiments on the rNST had suggested that cells within the gustatory NST could be inhibited by GABA and excited by the $GABA_A$ receptor antagonist, bicuculline methodide (BICM), suggesting a tonic GABAergic inhibitory network within this region (Liu, H. *et al.*, 1993; Wang, L. and Bradley, R. M., 1993). When GABA was microinjected into the hamster NST *in vivo*, taste-responsive neurons showed a dose-dependent inhibition of spontaneous

and evoked activity and their responses to taste stimulation were enhanced in a dose-dependent manner by BICM; 63% of the taste-responsive cells in the NST were modulated by GABAergic mechanisms in these experiments (Smith, D. V. and Li, C. S., 1998). The responses of all tastants were enhanced by BICM administration, showing that particular neurons, but not particular stimuli, are modulated by GABAergic inhibitory circuits. The result of the removal of GABAergic inhibition was an increase in the breadth of responsiveness of NST neurons to gustatory stimulation as the cells became more responsive to all stimuli, similar to the effects on tuning seen in other sensory systems following BICM (Kyriazi, H. T. *et al.*, 1996; Lazareva, N. A. *et al.*, 1997).

One source of inhibition of NST gustatory neurons arises from the gustatory cortex (GC), which sends descending connections to the NST (van der Kooy, D. *et al.*, 1984). Stimulation of GC results in both excitation and inhibition of the activity of taste neurons in the NST (Di Lorenzo, P. M. and Monroe, S., 1995). Both electrical stimulation of the GC and excitation produced by the glutamate analog DL-homocysteic acid (DLH) produced either excitation or inhibition in about 34% of taste-responsive cells in the hamster NST (Smith, D. V. and Li, C., 2000). The inhibition produced by GC stimulation was blocked by infusion of BICM into the vicinity of the recorded cell in the NST. Of the eight cells inhibited by GC stimulation, seven were most responsive to NaCl, suggesting that cortical-evoked inhibition of NST activity may be somewhat stimulus-specific (Smith, D. V. and Li, C., 2000), although the effects of GC stimulation on the responses to NaCl themselves were not tested in this study. Gustatory neurons in both the PbN (Kobashi, M. and Bradley, R. M., 1998) and insular cortex (Ogawa, H. *et al.*, 1998) are also modulated by GABAergic mechanisms.

4.15.2.2.4.(iii) Peptides: substance P and opioids

Immunocytochemical studies show that there are substance P (SP)-containing neurons and fiber terminals within the rNST (South, E. H. and Ritter, R. C., 1986; Davis, B. J. and Kream, R. M., 1993). In experiments on *in vitro* brainstem slices in rats (King M. S. *et al.*, 1993), SP transiently depolarized 80 of 117 (68%) rNTS neurons in a dose-dependent manner. Submicromolar concentrations of SP had potent excitatory effects, and the half-maximal response occurred at 0.6 μM. The depolarizing effect of SP was accompanied by an increase in input resistance in 81% of the responsive neurons and persisted in low Ca^{2+} and high Mg^{2+} saline as well as in the presence of tetrodotoxin (TTX), suggesting direct postsynaptic action of SP on the recorded neurons. SP also hyperpolarized four neurons (4%) and had no effect on 33 cells (28%). When gustatory neurons were recorded *in vivo* from hamster NST, about 48% were excited by microinjection of SP into the nucleus, whereas 9% were inhibited (Davis, B. J. and Smith, D. V., 1997). In this experiment, only NaCl was used as a taste stimulus, so it is as yet unclear whether SP produces differential effects according to stimulus. However, the responses to NaCl were clearly enhanced by SP.

Endogenous opiates have been implicated in gustatory palatability (e.g., Rideout, H. J. and Parker, L. A., 1996) and earlier studies had shown that systemic administration of morphine resulted in inhibition of taste-evoked multiunit activity in the rat PbN (Hermann, G. E. and Novin, D., 1980) Injection of naltrexone (NLTX), a nonselective opioid receptor antagonist, into the NST blocks feeding induced by neuropeptide Y administration into the paraventricular nucleus (Kotz, C. M. *et al.*, 1997), implicating an opioid-mediated influence within the NST. Further, μ-opioid receptors are expressed by rNST neurons that receive synaptic input from neurons in the central nucleus of the amygdala (Pickel, V. M. and Colago, E. E., 1999), an area known to provide modulatory input to the gustatory NST (Li, C. S. *et al.*, 2002a). Within the gustatory portion of the rNST, there are both nerve fibers and cell bodies expressing methionine enkephalin (met-ENK) immunoreactivity (Davis, B. J. and Kream, R. M., 1993). In neurons recorded *in vivo* from the hamster NST, microinjection of met-ENK reversibly reduced the responses of 39 of 165 (23.6%) taste-responsive neurons in a dose-dependent manner (Li, C. S. *et al.*, 2003). This inhibition was blocked by NLTX, although NLTX alone had no effect, suggesting that opioid inhibition in these neurons is not tonic. Thus, along with GABAergic mechanisms, opioids exert an inhibitory effect on gustatory processing in the NST.

4.15.2.2.4.(iv) Other neurotransmitters: dopamine, acetylcholine, and nitric oxide

Less is known about the function of other neurotransmitters in the gustatory NST, although there is some evidence for dopaminergic, cholinergic, and nitrergic mechanisms. Within the gustatory portion of the hamster NST, neurons expressing tyrosine hydroxylase and dopamine-β-hydroxylase have been described (Davis, B. J. and Jang, T., 1988b). In electron micrographic studies,

(Davis, B. J., 1998) demonstrated that NST neurons expressing tyrosine hydroxylase received synaptic input directly from chorda tympani nerve axons, suggesting that these neurons are second-order gustatory cells. The rNST also contains neurons that express nitric oxide synthase (NOS), the synthetic enzyme for nitric oxide and stain for NADPH diaphorase (NADPHd), a marker for NOS (Ruggiero, D. A. *et al.*, 1996; Travers, S. P. and Travers, J. B., 2006). In fact, about 15–20% of the neurons that express Fos-like immunoreactivity in response to gustatory stimulation with quinine or citric acid are double-labeled for NADPHd suggesting that nitric oxide may be a transmitter in a subset of taste cells. Further, many of these Fos neurons intermingle with NOS fibers, implying that nitric oxide could modulate taste responses (Travers, S. P. and Travers, J. B., 2006). However, to date, there are no functional data showing a role for dopamine or nitric oxide in gustatory processing. On the other hand, application of acetylcholine (ACh) to cells recorded in rat brain slices through the rNST show that many of these neurons are modulated by ACh, mediated through both nicotinic and muscarinic ACh receptors (Uteshev, V. V and Smith, D. V., 2006). Nicotinic responses, which were always excitatory, were mediated by either $\alpha 7$ or non-$\alpha 7$ nicotinic AChRs and comprised about 66% (50/76) of the cells examined. Responses mediated by muscarinic AChRs were seen in 42% (31/73) neurons tested. These responses were inhibitory near the resting potential, resulting in a block of evoked spikes. Extensive acetylcholinesterase (AChE) immunostaining is closely associated with the terminal fields of both the chorda tympani and glossopharyngeal nerves in the rNST (Barry, M. A. *et al.*, 2001) and there are neurons expressing choline actetyltransferease (ChAT) in the medial portion of the rNST (Ruggiero, D. A. *et al.*, 1990). These latter neurons are part of the parasympathetic preganglionic neurons of the inferior salivatory nucleus (Contreras, R. J. *et al.*, 1980), which could conceivably modulate taste activity as a consequence of parasympathetic activity. There are as yet no data on cholinergic modulation of taste responses *in vivo*, nor is it clear whether all of the cholinergic input to this area is derived from these parasympathetic neurons.

4.15.2.2.5 Descending pathways from forebrain targets: modulation of nucleus of the solitary tract and parabrachial nuclei

As delineated above, decerebration has been shown to modulate brainstem gustatory activity, indicating that the responsiveness of brainstem gustatory neurons reflects not only sensory input from the taste receptors, but descending influences from forebrain circuits. There are direct descending projections from the GC, the lateral hypothalamus, the central nucleus of the amygdala, and the bed nucleus of the stria terminalis to both the NST and PbN gustatory regions (van der Kooy, D. *et al.*, 1984; Moga, M. M. *et al.*, 1990b; Allen, G. V. *et al.*, 1991; Halsell, C. B., 1998). A series of recent experiments on both rats and hamsters has demonstrated that each of these forebrain targets of the gustatory system provides modulatory control over taste-responsive neurons in the NST and PbN (Figure 2).

4.15.2.2.5.(i) Gustatory cortex

When the activity of GC was blocked by local infusion of procaine, both increases and decreases in the taste responses were recorded from the rat NST (Di Lorenzo, P. M. and Monroe, S., 1995) and PbN (Di Lorenzo, P. M., 1990), showing that these cells can be either facilitated or inhibited by cortical influences. Similar results were seen as a result of electrical or chemical stimulation of the GC in hamsters (Smith, D. V. and Li, C., 2000). Of 50 neurons recorded from the hamster NST, 17 (34%) were modulated by ipsilateral cortical stimulation. About half of these (9/17) were excited and half (8/17) were inhibited. Although the excitatory effects were distributed across different cell types, the inhibitory effects were significantly more common in NST cells responding best to NaCl. In a more recent experiment, in which stimulating electrodes were implanted bilaterally in the GC, a slightly greater influence of the contralateral cortex was noted: 16 of 50 cells (32%) were modulated ipsilaterally, whereas 20 of 50 (40%) responded to contralateral stimulation (Smith, D. V. *et al.*, 2004). Eleven of these neurons received converging input from both sides of the cortex, so that among the 50 cells recorded, 25 (50%) were modulated by one or both sides. A similar experiment on the rat showed that taste-responsive neurons in the PbN are also modulated by GC stimulation, with both inhibitory and excitatory responses (Lundy, R. F., Jr. and Norgren, R., 2004a). Both of these stimulation studies are compatible with the earlier studies in which the cortex was anesthetized with procaine, which resulted in both increased and decreased taste responses in PbN and NST (Di Lorenzo, P. M., 1990).

4.15.2.2.5.(ii) Lateral hypothalamus

Cells within the lateral hypothalamus respond to taste stimuli

applied to the oral cavity (Norgren, R., 1970; Yamamoto, T. *et al.*, 1989a) or alter their activity during food ingestion (Sasaki, K. *et al.*, 1984; Ono, T. *et al.*, 1986). There are descending projections from the lateral hypothalamus to both the PbN and NST (van der Kooy, D. *et al.*, 1984; Moga, M. M. *et al.*, 1990a). Earlier studies had suggested that stimulation of the lateral hypothalamus enhanced the responses of rat NST neurons evoked by chorda tympani nerve stimulation (Bereiter, D. *et al.*, 1980) or by electrical stimulation of the tongue (Matsuo, R. *et al.*, 1984). Electrical and chemical stimulation of the lateral hypothalamus in hamsters produced orthodromic modulation of half (49/99) of NST taste-responsive neurons (Cho, Y. K. *et al.*, 2002b) (Grossman, S. P. *et al.*, 1978; Frank, R. A. and Stutz, R. M., 1982). Most of these effects (44/99) were excitatory, as shown in the example in Figure 7.

Thus about half the taste-responsive cells of the NST are modulated (mostly excited) by the lateral hypothalamus. Stimulation of this region of the brain induces feeding behavior and, conversely, lateral hypothalamic lesions reduce food intake (Grossman, S. P. *et al.*, 1978; Frank, R. A. and Stutz, R. M., 1982), and tthese effects have been shown to interact with taste-guided behavior (Murzi, E. *et al.*, 1986; Touzani, K. *et al.*, 1990; Conover, K. L. and Shizgal, P., 1994). Thus, it is interesting to speculate that the lateral hypothalamus could enhance the signal-to-noise ratio in NST taste neurons during bouts of feeding (Cho, Y. K. *et al.*, 2002b). Lateral hypothalamic stimulation has also been shown to modulate taste activity in neurons of the rat PbN, although the excitatory and inhibitory influences were equal (Lundy, R. F., Jr. and Norgren, R., 2004a).

4.15.2.2.5.(iii) Central nucleus of the amygdala

The central nucleus of the amygdala contains neurons that respond differentially to hedonically positive and negative taste stimuli (Nishijo, H. *et al.*, 1998) and both the central nucleus and basolateral amygdala are involved in CTA learning (Yamamoto, T. *et al.*, 1994). The central nucleus of the amygdala provides a direct descending projection to both the NST and PbN (Norgren, R., 1976; Veening, J. G. *et al.*, 1984; Halsell, C. B., 1998). When stimulating electrodes were implanted bilaterally in the hamster central nucleus, 36 of 109 NST taste-responsive neurons (33%) were orthodromically modulated; 33 of these cells were excited and 3 were inhibited. Interestingly, those neurons that were modulated by the central nucleus of the amygdala had a significantly smaller response to taste stimuli than those that were not modulated. However, like the modulation of cells by the lateral hypothalamus, there was no specific effect on any one stimulus or cell type within the NST. On the other hand, in the PbN, Lundy R. F., Jr. and Norgren R. (2001) reported that stimulation of the central nucleus of the amygdala in the rat produced mostly suppressive effects, with an overall effect of enhancing the salience of the response to NaCl, suggesting that descending control from the amygdala could play a role in the mechanisms of sodium appetite. Stimulation of the central nucleus of the amygdala also produced more inhibition than excitation in another experiment (Tokita, K. *et al.*, 2004), in which it was shown that alterations in PbN neuronal responses to NaCl following CTA are eliminated by decerebration. These authors argued that descending influences from the central nucleus are important for the gustatory changes seen in the PbN following conditioning. Thus, one of the roles of the descending influence of the central nucleus of the amygdala on both the PbN and NST may be to produce alterations in brainstem responding following CTA, such as changes in taste reactivity seen, for example, to sucrose following aversive conditioning (Grill, H. J., 1985).

In both the NST (Cho, Y. K. *et al.*, 2003) and PbN (Lundy, R. F., Jr. and Norgren, R., 2004a), taste-responsive cells are often modulated by more than one forebrain structure. For example, of 113 cells in the hamster NST that were modulated by stimulation of either the lateral hypothalamus or central nucleus of the amygdala, 52 were responsive to stimulation of both sites. In the rat PbN, 60 neurons were tested for their responses to stimulation of the GC, central nucleus of the amygdale and lateral hypothalamus and 53 of them were modulated; 37 of them responded to more than one of these sites, with 17 neurons influenced by two sites and 20 by all three. In both the NST and PbN studies, the influence of different sites was most often similar, although there were cells that were excited by one site and inhibited by another. In a recent study of the effects of CeA and LH stimulation on neurons of the hamster PbN, most cells of the PbN were antidromically activated by stimulation of these sites (Li, C. S. *et al.*, 2005), which are synaptic targets of output neurons of the PbN (Norgren, R., 1976). Of 101 neurons tested in this study, 83 were antidromically driven by either the lateral hypothalamus or central nucleus of the amygdala and 57 of these by both, indicating a direct projection from the PbN to both of these areas. Only a small number of cells were

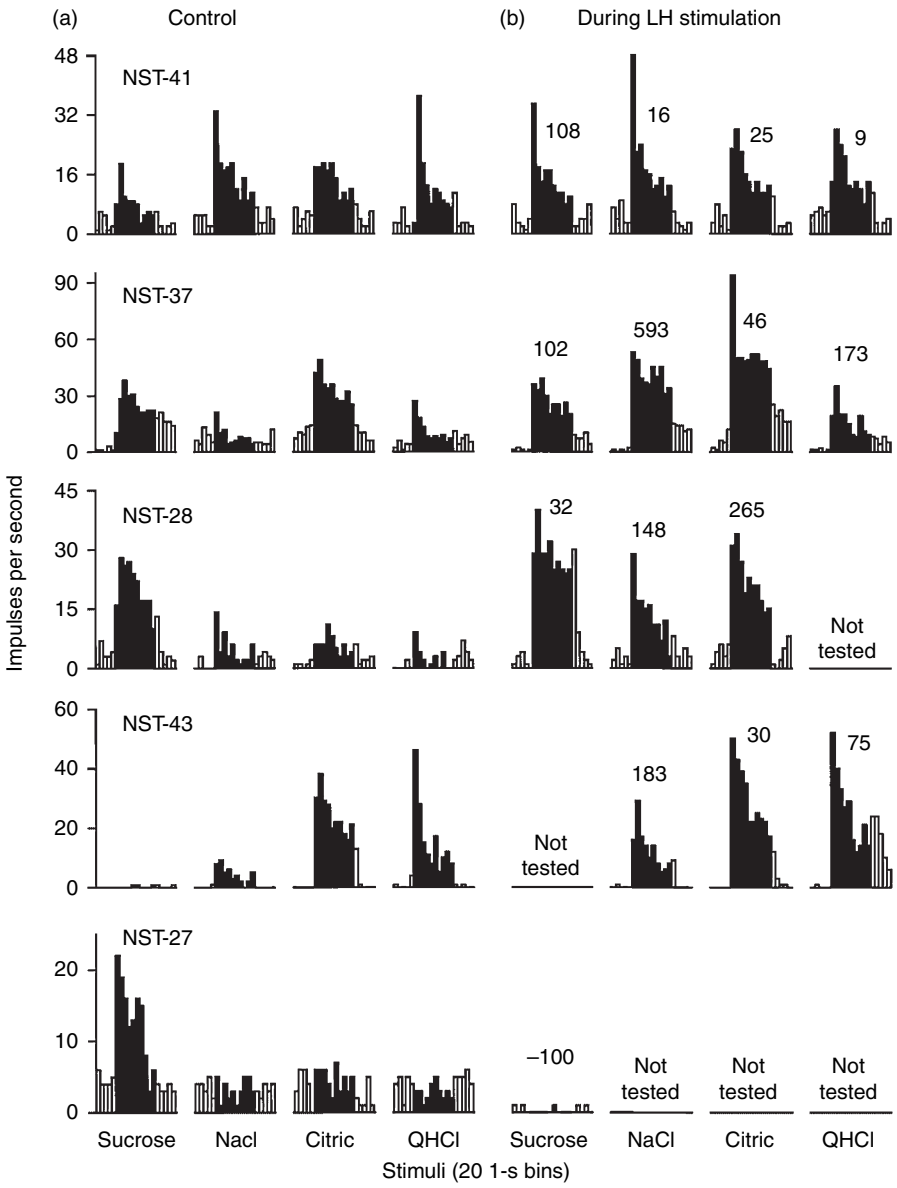

Figure 7 Effects of electrical stimulation of the lateral hypothalamus (LH) on taste-evoked responses in the rostral nucleus of the solitary tract (NST). Left: Gustatory responses in five neurons in the absence of LH stimulation. Right: Taste-evoked activity of these same neurons during concurrent stimulation (100 Hz, 0.2 ms pulses) using an intensity that was just subthreshold for altering spontaneous activity. As was typical for the entire population, the taste responses of most (4/5) of these neurons were amplified by activation of the LH. From Cho, Y. K. *et al.*, 2002b. Taste responses of neurons of the hamster solitary nucleus are enhanced by lateral hypothalamic stimulation. J. Neurophysiol. 87, 1981–1992, with permission.

orthodromically modulated, with five cells excited and eight inhibited by one of these forebrain areas. Clearly, there are complex descending influences on the gustatory responses of cells in both the NST and PbN.

4.15.2.2.5.(iv) Bed nucleus of the stria terminalis

In addition to the ventral projection of the PbN to the lateral hypothalamus and central nucleus of the amygdala, there is also a projection to the dorsolateral bed nucleus of the stria terminalis (Norgren, R., 1976), although to date there are no electrophysiological data showing gustatory responsiveness in this area. Nevertheless, the bed nucleus sends a descending projection to both the NST and the PbN (van der Kooy, D. *et al.*, 1984; Moga, M. M. *et al.*, 1990b; Whitehead, M. C. *et al.*, 2000). Stimulation of the

bed nucleus of the stria terminalis inhibited 29 of 101 hamster NST taste neurons, whereas only 7 were excited. All cell types were affected, although the number of NaCl-best neurons were fewer and citric acid-best greater among the modulated cells than expected by chance. Although we know that various subnuclei of the bed nucleus of the stria terminalis are implicated in a number of neural systems, including those involved in responses to stress (Morley, J. E. and Levine, A. S., 1980; Herman, J. P. and Cullinan, W. E., 1997; Cecchi, M. *et al.*, 2002), and in motivation, reward, and drug addition (Walker, J. R. *et al.*, 2000; Macey, D. J. *et al.*, 2003), how it plays a role in taste processing is not clear. Descending feedback from this region could conceivably be involved in the effects of stress on eating behavior (Morley, J. E. and Levine, A. S., 1980; Fullerton, D. T. *et al.*, 1985; Walker, J. R. *et al.*, 2000; Hagan, M. M. *et al.*, 2003; Macey, D. J. *et al.*, 2003).

These kinds of stimulation experiments have demonstrated extensive centrifugal modulation of brainstem gustatory activity, in both the NST and PbN. Essentially, every forebrain target of the gustatory system, including the GC, lateral hypothalamus, central nucleus of the amygdala, and bed nucleus of the stria terminalis exerts a descending modulatory influence on the processing of taste information. The hypothalamus and amygdala have predominantly an excitatory effect on the NST, whereas the cortex and bed nucleus produce significant inhibition of medullary taste responses. This extensive neural substrate no doubt underlies the modulation of taste activity by physiological and experiential factors and further research should be directed toward determining how these pathways are engaged by alterations in blood glucose, gastric distension, CTA, and other physiological conditions known to alter taste activity.

4.15.3 Gustatory Responsiveness of Forebrain Neurons

Although we know a great deal about the responsiveness of brainstem gustatory neurons, there are also data on gustatory areas beyond the pons, including the gustatory thalamic area, the taste cortex, and some regions of the limbic forebrain, including the lateral hypothalamus, central nucleus of the amygdala, nucleus accumbens, and ventral pallidum. The types of cells seen in brainstem areas, that is, sucrose-best, NaCl-best, etc., are also evident in more rostral nuclei. However, cells that appear to be tuned to stimulus palatability more than taste quality *per se* are also evident, especially in the limbic regions. Whereas the data on brainstem taste responses are almost exclusively from the rodent, and with notable exceptions (Nakamura, K. and Norgren, R., 1991; Nishijo, H. and Norgren, R., 1991; Nishijo, H. *et al.*, 1991; Nakamura, K. and Norgren, R., 1993), mostly from anesthetized preparations, much of the forebrain data is from primates, and regardless of species, frequently studies utilize awake, behaving preparations. Studies based on functional imaging in humans further provide a novel perspective for studying forebrain gustatory function. Due to space constraints, we will concentrate on cortical and limbic processing of taste information.

4.15.3.1 Taste Cortex

4.15.3.1.1 Organization and relationship to other sensory modalities

As discussed in Chapter Gustatory Pathways in Fish and Mammals, primary GC in both rodents and primates is located in insular cortex (Pritchard, T. C. *et al.*, 1986; Kosar, E. *et al.*, 1986a; 1986b). In primates, the gustatory insular cortex is buried in the Sylvian fissure but the primary gustatory area extends from the insula onto the opercular cortex (Pritchard, T. C. *et al.*, 1986). In both rodents and primates, gustatory signals reach the insular cortex via a relay in the most medial part of the ventroposteromedial nucleus of the thalamus (VPMpc). However, in rodents taste information reaches the thalamus only after making a synapse in the parabrachial nucleus (Norgren, R. and Leonard, C. M., 1971; 1973); in primates there is a direct rNST–thalamic pathway (Beckstead, R. M. *et al.*, 1980). Although a gustatory relay in the primate PBN was initially considered unlikely, recent human imaging studies hint that a pontine relay may be a possibility in these species as well (Small, D. M. *et al.*, 2003; Topolovec, J. C. *et al.*, 2004). However, because the rostral pole of the monkey NST does not project to the PBN (Beckstead, R. M. *et al.*, 1980), nor are anterior tongue taste responses apparent in the pons (Pritchard, T. C. *et al.*, 2000), any gustatory PBN representation in primates is likely to arise from posterior tongue or pharyngeal taste buds (discussed in Travers, S. P., 1993).

In primates, taste-responsive neurons are also located in the orbitofrontal cortex and this area has typically been considered to constitute secondary GC (Baylis, L. L. *et al.*, 1995); taste-related activity

has recently been reported in an analogous region in rodents as well (Gutierrez, R. *et al.*, 2006). Further, emerging data, including human imaging studies, suggest that there is a high degree of complexity in cortical processing such that multiple hierarchical gustatory relays may be located within both the insular and orbitofrontal cortex (discussed in Pritchard, T. C. and Norgren, R., 2004). In addition to confirming the involvement of insular/opercular and orbitofrontal cortex in representing gustatory information in humans, imaging studies implicate other cortical areas, most consistently the cingulate, but also the posterior parietal or prefrontal, in processing some aspects of the gustatory signal (e.g., Small, D. M. *et al.*, 2003; 2004).

Cortical taste representation is complex with regard to its gustatory orotopic organization and relationship to the representation of innocuous somatosensation, visceral sensation, pain, and olfactory signals. Consistent with lower levels of the neuraxis, at least in subprimates, taste inputs to the cortex are arranged orotopically. Based on electrically stimulating the chorda tympani and glossopharyngeal nerves and recording evoked potentials (Benjamin, R. M. and Pfaffmann, C., 1955; Yamamoto, T. and Kawamura, Y., 1975; Yamamoto, T. *et al.*, 1980) or single units (Hanamori, T. *et al.*, 1997), information from the anterior oral cavity is located more anteriorly; that from the posterior oral cavity more posteriorly. A recent experiment using intrinsic optical imaging suggests that taste quality may also have a systematic topographic organization along the anterior–posterior axis in cortex. Although not exhibiting complete segregation, activity elicited by sweet and salty tastants (sucrose and NaCl) was located more anteriorly than that produced by stimulation with sour or bitter stimuli (citric acid and quinine) (Accolla, R. *et al.*, 2007).

4.15.3.1.1.(i) Taste–visceral relationships

Gustatory orotopy is actually part of a more extensive orderly topography in insular cortex, again mirroring the brainstem and thalamic organizations. The representation of inputs arising from the postoral gastrointestinal tract and other visceral organs extends posteriorly from the posterior oral cavity gustatory representation (Cechetto, D. F. and Saper, C. B., 1987; Squire, L. R. *et al.*, 2003). The degree of segregation or overlap between taste signals and visceral signals has not been thoroughly explored, but some degree of convergence onto single neurons in rodents seems likely (Yamamoto, T. *et al.*, 1989b; Hanamori, T. *et al.*, 1998a; 1998b; but see Cechetto, D. F. and Saper, C. B., 1987). In nonhuman primates, single-unit responses in the insula evoked by visceral stimulation have mostly been assessed indirectly, by noting how satiety affects gustatory responses. In the insular cortex, feeding a monkey to satiety does not alter the magnitude of gustatory responses (Yaxley, S. *et al.*, 1988), suggesting segregation between gustatory and visceral signals in this region. However, this segregation in the primary GC seems to be a major difference between monkeys and rodents, as in rodents, taste and visceral signals converge even at brainstem levels (e.g., Giza, B. K. *et al.*, 1992; Hajnal, A. *et al.*, 1999; Baird, J. P. *et al.*, 2001). In monkeys, convergence of taste and visceral signals has been reported to be a higher-level function first observed in the orbitofrontal cortex (Rolls, E. T. *et al.*, 1989; Pritchard, T. C. *et al.*, 2005), and is reflected in a decline of taste responses coincident with the onset of satiety. Interestingly, the decline in gustatory responsiveness is limited to the stimulus used to induce satiation, and this neural change parallels a specific change in behavior, a phenomenon termed sensory-specific satiety (Rolls, B. J. *et al.*, 1981; 1986). Human imaging studies further demonstrate that gustatory-evoked activity in the orbitofrontal cortex is altered by satiety (Kringelbach, M. L. *et al.*, 2003), although, in contrast to the monkey, insular responses also seem to be affected (Kringelbach, M. L. *et al.*, 2003; Smeets, P. A. *et al.*, 2006; Uher, R. *et al.*, 2006).

4.15.3.1.1.(ii) Taste–somatosensory relationships

As with lower levels of the neuraxis, gustatory responses in primary taste cortex have a proximate relationship with the representation of oral somatosensory, as well as visceral sensory inputs. The primary somatosensory cortex (S1) is comprised of somatosensory-specific neurons. In primates, S1 is located in Brodmann's areas 3a, 3b, 1, and 2. S1 in rodents is in a homologous location. In both species, S1 is medial to the primary gustatory representation in insular cortex. The somatotopy in S1 is arranged such that the oral representation is most lateral and abuts the gustatory-responsive zone (Squire, L. R. *et al.*, 2003). The extent to which there is a segregated region, comprised only of taste-responsive neurons, remains an unanswered question. There is evidence for an orderly medial-to-lateral progression of oral tactile, thermal, and gustatory responses, suggestive of a certain degree of segregation (Kosar, E. *et al.*, 1986a). However, other data indicate that cells responsive to oral mechanical stimulation are intermingled with taste cells in this region. Further, a large subset of

gustatory cortical neurons also respond to oral mechanical stimuli (Katz, D. B. *et al.*, 2001; Ogawa, H. and Wang, X. D., 2002; Wang, X. and Ogawa, H., 2002). In fact, taste cells with oral mechanical RF's have also been reported to receive additional inputs from remote regions of the glaborous skin of the body (Wang, X. and Ogawa, H., 2002). Thus it is tempting to conclude that nearly all cortical taste neurons also have a tactile input. However, as recently pointed out by Lundy R. F., Jr. and Norgren R. (2004b), only a few studies have actually tested responsiveness of insular neurons to both modalities, particularly in a quantitative fashion. Thus, though convergence seems pervasive, the relative magnitudes of taste and somatosensory responses within individual neurons are unclear (Wang, X. and Ogawa, H., 2002). Furthermore, since some converging somatosensory responses appear nociceptive since they require high pressures or pinch (Ogawa, H. and Wang, X. D., 2002), a more thorough examination is required to rule out nonspecific effects, such as arousal. Nevertheless, the apparent multimodal nature of many neurons in primary taste cortex raises the question of how these neurons are able to clearly code the presence of a taste apart from somatosensory stimuli. A proposed solution to this conundrum is the interesting suggestion that the different modalities are coded by temporally distinct components of the response; that is, the initial 0.5 s of the response codes somatosensory events and the subsequent response codes gustatory-specific information (Katz, D. B. *et al.*, 2001).

A novel hypothesis regarding the relationship of gustatory to somatosensory cortex was recently suggested by Kaas J. H. (2005) . Observations in primates have revealed an ever-expanding region for somatosensory cortex, indicating that it is much more extensive than evident in the original descriptions. Neurophysiological mapping studies indicate that multiple, higher-level somatosensory maps extend laterally from areas 3a, 3b, and 1 into the insula. These regions receive spinal and extraoral trigeminal, in addition to an intraoral representation, and arguably encompass what has classically been considered primary GC (e.g., Jain, N. *et al.*, 2001). These findings prompted Kaas J. H. to propose the provocative idea that there may be no pure primary GC, but instead, that the insular taste area is an integral part of the intraoral representations embedded in higher-order somatosensory zones. He further speculates that this may account for the common observation that single-unit studies observe only a small fraction of neurons in the insular GC that actually respond to taste stimulation (e.g., Scott, T. R. *et al.*, 1986; Plata-Salaman, C. R. *et al.*, 1996; Wang, X. and Ogawa, H., 2002). Although such a radical restructuring of the concept of primary GC is intriguing, further experiments are required for verification. Another possibility is that it is simply difficult to precisely locate the relatively small region receiving direct inputs from the gustatory thalamus (Pritchard, T. C. *et al.*, 1986), making it equally plausible that there is a small, more purely taste core adjacent to a larger area with mixed inputs.

The complexity of the insular region is also highlighted by discoveries about the nociceptive pathway. Neuroanatomical (Jasmin, L. *et al.*, 2004), neurophysiological (Ito, S. I., 1998; Hanamori, T. *et al.*, 1998b; Gauriau, C. and Bernard, J. F., 2004), and functional imaging studies (Petrovic, P. *et al.*, 2002; Bingel, U. *et al.*, 2003; Schweinhardt, P. *et al.*, 2006) in humans have identified the insular cortex as a major locus for processing pain information. These signals reach the insula via multiple pathways, including a spinoparabrachial pathway that relays through the ventroposteromedial and nearby regions of the thalamus (Menendez, L. *et al.*, 1996; Bester, H. *et al.*, 1999; Krout, K. E. and Loewy, A. D., 2000; Jasmin, L. *et al.*, 2004), and in primates through an additional evolutionarily newer direct spinal–thalamic–insular pathway that synapses in a posteriorly adjacent distinct nucleus in the thalamus, the posterior portion of the ventromedial nucleus (Craig, A. D., 2004). In fact, these pathways appear to carry not only nociceptive signals, but also thermal signals (Craig, A. D. *et al.*, 2000; Craig, A. D., 2003a; 2003b). The representation of pain, thermal, visceral, and taste information in the insular cortex has led to the suggestion that it is a region unified for processing the homeostatic state of the body (Craig, A. D., 2003a; 2003b).

4.15.3.1.1.(iii) Taste–olfactory relationships

Because the everyday appreciation of food and drink does not rely on taste alone, but rather on the combination of taste with oral somatosensory and olfactory sensations, it is especially important to understand where these two types of chemical signals converge centrally. The first point of convergence appears to be in the forebrain, but neither the initial site of convergence nor the responsible pathway(s) is entirely clear. Furthermore, species differences are likely. In the rodent, anatomical data suggest that olfactory information can impact the insular cortex via a least two routes, a direct projection from the olfactory bulb (Shipley, M. T. and Geinisman, Y., 1984), or a connection from the endopyriform

nucleus (Behan, M. and Haberly, L. B., 1999; Fu, W. *et al.*, 2004). However, whether the insular area described in these studies is actually gustatory is not certain, nor is it clear that olfactory signals actually converge on a significant proportion of taste cells in rodent insular cortex. Other sites of forebrain convergence are also possible. A recent optical imaging/recording brain slice study demonstrated that signals from the pyriform (olfactory) and dysgranular (probably taste) insular cortex both reach the endopyriform nucleus, and converge on single cells (Fu, W. *et al.*, 2004). In addition, another forebrain region, the amygdalopyriform transition area, seems to receive relatively direct olfactory and gustatory information over a different route (Santiago, A. C. and Shammah-Lagnado, S. J., 2005). In this case, the olfactory inputs arise from neurons in the pyriform cortex, whereas putative gustatory inputs arise from the parabrachial nucleus. That the parabrachial input is gustatory seems quite likely because the cells of origin depicted in photomicrographs are centered in precisely the same part of the waist region where electrophysiological studies routinely report taste responses (e.g., Norgren, R. and Pfaffmann, C., 1975). There has not been a systematic neurophysiological investigation of gustatory–olfactory convergence in the rodent forebrain, although one report did document a few such convergent cells in insular cortex (Yamamoto, T. *et al.*, 1989b). In contrast, in the monkey, responses to both taste and olfactory stimulation have been recorded from significant populations of single neurons in the lateral orbitofrontal cortex (Rolls, E. T. and Baylis, L. L., 1994), although such convergence has not been observed in the insula. However, it may be premature to rule out taste–olfactory convergence in the insula. Indeed, as summarized by Small, D. M. and Prescott, J. (2005), human imaging studies reveal that olfactory stimuli activate the same insular and orbitofrontal regions as do tastants, although the obverse is not true for primary olfactory cortex. Imaging studies also indicate other cortical regions where taste and smell interact or overlap, with the anterior cingulate being particularly notable. Importantly, the human imaging studies point to critical integrative features of this convergence; that is, synergy between taste and olfactory signals occurs prominently with retronasal but not orthonasal olfactory signals (Small, D. M. *et al.*, 2005) and further requires that the taste and olfactory signals are congruent (Figure 8). Thus a

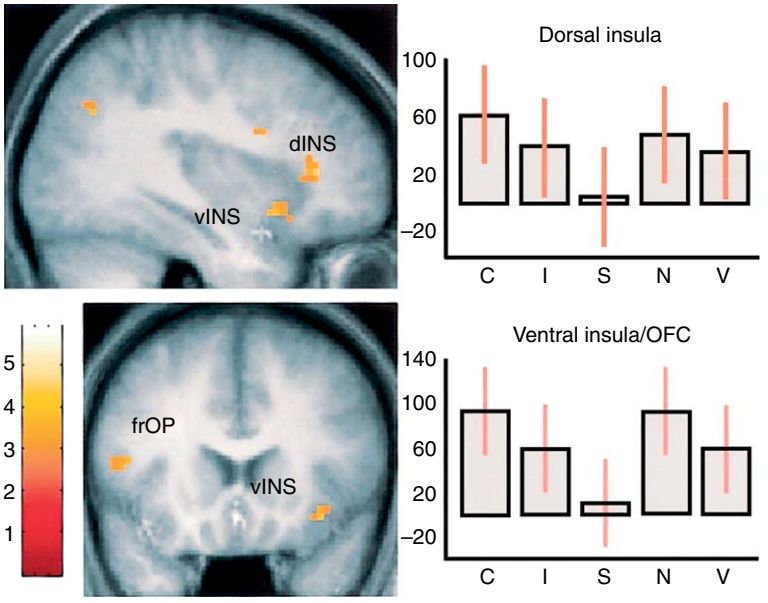

Figure 8 Functional magnetic resonance imaging (fMRI) activation of the insular region following presentation of a sweet stimulus (0.18 M sucrose) mixed with vanilla. Both the dorsal insula (primary gustatory cortex) and the ventral insula, a higher-order processing region, are activated in a supra-additive fashion by this congruent, familiar mixture. The graphs on the right depict these results quantitatively and compare the sucrose–vanilla congruent mixture (C), with an incongruent mixture (NaCl–vanilla, I), and with each of the components alone. S, sucrose; N, NaCl; V, vanilla. (a) From Small, D. M., Voss, J., Mak, Y. E., Simmons, K .B., Parrish, T., and Gitelman, D. 2004. Experience-dependent neural integration of taste and smell in the human brain. J. Neurophysiol. 92, 1892–1903, with permission.

familiar olfactory–taste pair, vanilla–sweet, yielded superadditive functional magnetic resonance imaging (fMRI) responses in the insula and several other forebrain regions but an unfamiliar, incongruent pair, vanilla–salty, did not (Small, D. M. *et al.*, 2004).

4.15.3.1.2 Gustatory cell types and processing

4.15.3.1.2.(i) Response profiles and firing rates

Compared to other sensory systems, the transformation of gustatory information by cortical circuits at first glance seems subtle. Some differences have been reported, for example, a minority of insular neurons in the rat appeared to code palatability rather than quality (Yamamoto, T. *et al.*, 1989b). Nevertheless, in both rodents (Yamamoto, T. *et al.*, 1985; 1989b; Ogawa, H. *et al.*, 1992) and primates (Yaxley, S. *et al.*, 1990), many studies of primary GC have yielded reports of best-stimulus neurons quite similar to those in peripheral nerves and brainstem. The same is true for neurons in caudolateral (secondary) GC (Baylis, L. L. and Rolls, E. T., 1991) though, as noted above, more modulation by satiety and interaction with other modalities probably occurs in this higher-order cortex. On the face of it, the lack of an obvious transformation at the cortical level is not due to using restricted stimulus arrays, or suppressed cortical activity in anesthetized preparations. A significant number of these studies used large numbers of tastants (e.g., Smith-Swintosky, V. L. *et al.*, 1991; Plata-Salaman, C. R. *et al.*, 1992; 1993; Scott, T. R. *et al.*, 1994; Plata-Salaman, C. R. *et al.*, 1995; Scott, T. R. *et al.*, 1999), included taste mixtures (Miyaoka, Y. and Pritchard, T. C., 1996; Plata-Salaman, C. R. *et al.*, 1996), and many were carried out in awake preparations.

Though the relative response profiles appear similar to those at lower levels of the neuraxis, it is notable that lower response rates are often characteristic of cortical taste cells. In addition, in contrast to the concentrated populations of taste neurons found in the brainstem, gustatory cortical neurons often appear to be intermingled with a larger population of nongustatory cells (e.g., Scott, T. R. *et al.*, 1986; Plata-Salaman, C. R. *et al.*, 1996; Wang, X. and Ogawa, H., 2002). The reason for this apparent sparseness is not known. As discussed above, Kaas J. H. (2005) suggests that one possibility is that multiple gustatory cortical regions are intertwined with secondary somatosensory cortex; that is, there is no pure GC. Another possibility is suggested by the findings of Pritchard T. C. *et al.* (2005). These investigators recently explored a different cortical area in monkey, the medial orbitofrontal cortex, a region implicated in taste function by anatomical experiments. In this previously unexplored area, the proportion of taste cells was markedly higher than in many other cortical studies. A careful reconstruction of recording sites showed that the incidence of gustatory cells was highly dependent upon the exact recording location; the concentrated core of taste-responsive neurons was very restricted. This suggests that some apparent sparseness in other studies could be due to the inherent technical difficulties in precisely targeting gustatory cortical regions, particularly in chronic recording studies. Interestingly, this study hints at another possible reason for sparseness since 24% of the neurons did not respond significantly to any of the four standard tastants but did respond to another (but unspecified) taste stimulus. This finding emphasizes that much remains to be learned about what constitutes the optimal stimulus configuration for cortical cells. Thus, cortical neurons may require more specific taste stimuli, combinations of taste stimuli or gustatory stimulation coincident with inputs from other modalities. For example, some taste cells may require particular combinations of learned taste and olfactory stimuli, as suggested by the human imaging studies (Small, D. M. *et al.*, 2004), or more speculatively, other learned combinations such as mixtures of different tastes, or of specific taste/texture combinations.

4.15.3.1.2.(ii) Breadth of tuning As discussed above, central neurons are, on average, more broadly tuned than those in the periphery. However, there are divergent reports concerning whether there is a systematic trend for tuning to broaden (Stapleton, J. R. *et al.*, 2006), sharpen (Scott, T. R. *et al.*, 1986; Rolls, E. T. *et al.*, 1990), or remain unchanged in cortex, compared to the brainstem (summarized in Spector, A. C. and Travers, S. P., 2005). At present, it is difficult to resolve this issue, in part, due to the variety of animal models (rodent, primate), types of preparation (acute anesthetized, chronic awake), recording procedures (single-unit sharp electrode; microwire bundles), and analytic techniques (summed activity, time course) used in the cortical experiments. Chronic, awake preparations arguably provide the most powerful tool for revealing the full range of responsiveness of central sensory neurons. This is particularly true for the cortex, because of the profound anesthetic suppression of sensory responses at this level of the nervous system (Sloan, T. B., 1998), as well as the active behaviors

sometimes required for revealing cortical response properties (e.g., Krupa, D. J. *et al.*, 2004). However, even when consideration is limited to awake preparations, varied tuning curves are apparent between studies. For example, although both groups of investigators recorded from a similar cortical region with microwire bundles, Stapleton, J. R. *et al.* (2006) reported an *H* value of 0.97, indicating that different stimuli evoked responses of roughly equal magnitude, whereas Yamamoto T. *et al.* (1989b) reported an average *H* value of 0.54, indicating much more specificity. In fact, although they tend to be more consistent, varied tuning curves can be observed within studies; in a typical instance, Pritchard T. C. *et al.* (2005) reported *H* values that ranged from 0.28 to 0.98. Thus, one conclusion emphasized in another recent review is that central tuning curves are inherently heterogeneous, including both narrowly and broadly tuned neurons best suited to subserve distinct functions, such as perception, motivation, and learning (Spector, A. C. and Travers, S. P., 2005).

4.15.3.1.2.(iii) Response time course, behavioral context Other more recent perspectives for devising a taste code involve alternate analyses which take time course and behavioral context into account (Katz, D. B. *et al.*, 2001; 2002; Hallock, R. M. and Di Lorenzo, P. M., 2006; Stapleton, J. R. *et al.*, 2006). In one experiment that analyzed just the initial 150 ms of the response, firing rates alone indicated almost no stimulus specificity, but when time course was considered, more specificity emerged (Stapleton, J. R. *et al.*, 2006). Another report of insular neurons not only observed very broadly tuned cells, but further found that the tuning curves of many neurons changed during a single experimental session, in parallel with decreases in the animal's attentional state (Fontanini, A. and Katz, D. B., 2006). Thus, unlike most previous studies, these recent reports provide little evidence for the classic best stimulus categories of neurons based on differential response magnitudes. Instead, they focus on the complex dynamic features of gustatory cortical responses and the key influence of behavioral state. It is important to point out, however, that the differences apparent in these more recent studies are probably due not only to differences in the type of analysis or behavioral paradigm, but also from differences in sampled populations. Although earlier studies similarly used awake animals, they also typically tested each stimulus on just a few trials and used simple response measures of summed activity; thus, taste responses were defined on the basis of relatively obvious changes in response rate (e.g., Scott, T. R. *et al.*, 1986; Yamamoto, T. *et al.*, 1989b; Rolls, E. T. *et al.*, 1990; Pritchard, T. C. *et al.*, 2005). In contrast, many current studies that take time course into account also tend to perform many repeated trials, a combination that adds a great deal of statistical power for identifying variations in neuronal firing. Such approaches extend the taste-responsive population to neurons that formerly would not have been considered to be gustatory (Katz, D. B. *et al.*, 2001). To what extent they include those neurons with more obvious responses is not entirely clear. Furthermore, the advantage conferred by this increased statistical power makes it important to demonstrate that these relatively subtle, but statistically demonstrable changes in time course or magnitude are behaviorally meaningful, as well as to attend to potential contributions from nearby oral thermal and tactile neurons. Nevertheless, it is clear that studies in behaving animals that use more complex behavioral paradigms and more powerful analytic techniques have great potential.

A particularly intriguing study has shed additional light on the function of rodent orbitofrontal cortex as it relates to rewarding tastes and voluntary ingestive behavior (Gutierrez, R. *et al.*, 2006; Travers, J. B., 2006). Neurons in this area of the cortex exhibited clear modulations of activity predictive of the beginning, occurrence, or end of a licking bout (Figure 9), and were more subtly modified depending on whether the rat was drinking sucrose or water. Thus, similar to what has been suggested for primate (Rolls, E. T. and Scott, T. R., 2003), rodent orbitofrontal cortex appears to monitor the reward value of tastes, and play a direct role in controlling reward-seeking behavior. Indeed, temporary inactivation of the rat orbitofrontal cortex with a $GABA_A$ agonist, muscimol, altered the microstructure of licking behavior. Overall intake remained relatively stable, but ingestion occurred in shorter bouts, indicative of a disruption of appetitive behavior (Gutierrez, R. *et al.*, 2006).

4.15.3.1.3 Neurotransmitters and neuromodulators in the insular cortex

4.15.3.1.3.(i) Excitatory amino acids In GC, a large variety of neurotransmitters, modulators, and their receptors comprise a rich substrate for processing sensory information. Taste responses in the majority of rat insular cortex neurons are dependent on glutamatergic input acting via non-NMDA, as well as NMDA receptors (Otawa, S. *et al.*, 1995), implying that

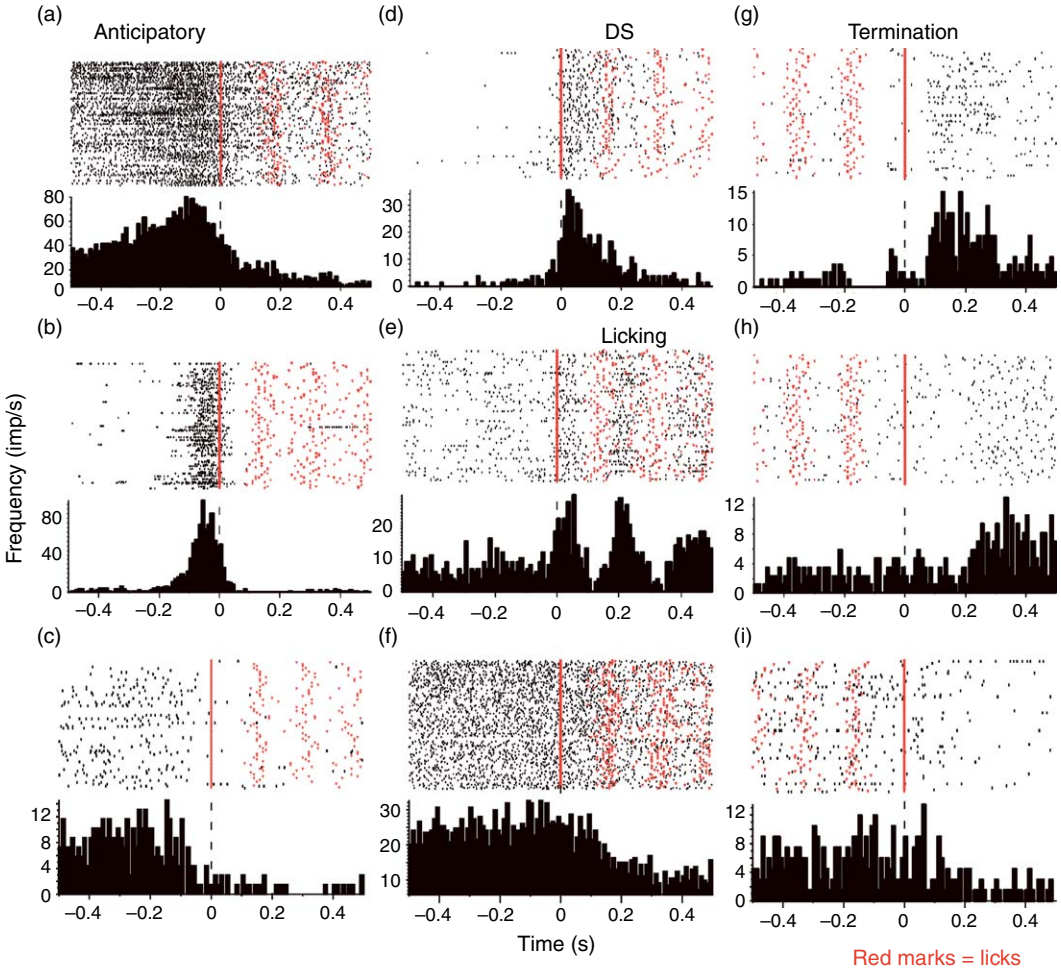

Figure 9 Responses of orbitofrontal cortex neurons prior to, during, and after bouts of licking 0.4 M sucrose. Each graph shows a different neuron, and depicts raster displays for multiple trials above a summed perievent histogram. The red dashes indicate licks. Each neuron exhibits a unique response pattern, but each column shows a given type based on whether the neuron alters its firing rate prior to a licking bout (Anticipatory), during the licking bout/stimulus (DS), or after the termination of the bout (Termination). From Gutierrez, R., Carmena, J. M., Nicolelis, M. A., and Simon, S. A. 2006. Orbitofrontal ensemble activity monitors licking and distinguishes among natural rewards. J. Neurophysiol. 95, 119–133, with permission.

glutamate is a key transmitter in the thalamocortical projection. Interestingly, in distinct contrast to the NST, NMDA receptor antagonists were as potent at reducing taste responses as non-NMDA antagonists, perhaps reflecting the greater plasticity inherent in cortical regions (Otawa, S. *et al.*, 1995). Ogawa and his group further demonstrated that both spontaneous and taste-evoked activity in the insular cortex is modulated by inhibitory amino acids, ACh, and peptides (Ogawa, H. *et al.*, 1998; 2000; Hasegawa, K. and Ogawa, H., 2007). These neurotransmitter systems likely play a major role in taste processing as 40–60% of insular cells were sensitive to iontophoresis of their antagonists and agonists.

4.15.3.1.3.(ii) Gamma-aminobutyric acid Similar to the NST, gustatory cortical neurons appear to be under tonic inhibition (Ogawa, H. *et al.*, 1998). Iontophoresis of the $GABA_A$ antagonist, bicuculline, onto insular cortical neurons yielded increases in spontaneous rate in 69% of the taste neurons sampled. Interestingly, only 51% of the entire population of insular cortical neurons (taste and nontaste combined) exhibited such an effect, suggesting that gustatory neurons may be subject to a greater degree of tonic inhibition than surrounding cells. Bicuculline exerted an effect on the taste responses themselves in a somewhat smaller (38%) but still significant proportion of neurons. As expected, taste responses

usually increased following bicuculline application; however, a more surprising outcome was that the increases were stimulus specific. These differential effects produced marked alterations in response profiles, including changes of best-stimulus and breadth of tuning (Figure 10).

Similar to the effects of bicuculline in the somatosensory cortex (Dykes, R. W. *et al.*, 1984; Tremere, L. *et al.*, 2001), receptive field size of gustatory neurons also increased when $GABA_A$ inhibition was removed. Before drug application most neurons had receptive fields restricted to the anterior tongue, but after bicuculline, inputs from the posterior tongue and palate became apparent. A particularly dramatic outcome was the recruitment of previously silent neurons that lacked both spontaneous and evoked activity; after bicuculline, these neurons became responsive to taste stimuli.

4.15.3.1.3.(iii) Acetylcholine ACh also affected taste responses in a substantial proportion (63%) of insular neurons but spontaneous rate was affected less often (17%; Hasegawa, K. and Ogawa, H., 2007). In contrast to bicuculline, iontophoresis of ACh both increased and decreased gustatory responses, though the action was usually in the same direction for different stimuli in a given cell. Nevertheless, within cells, responses to different

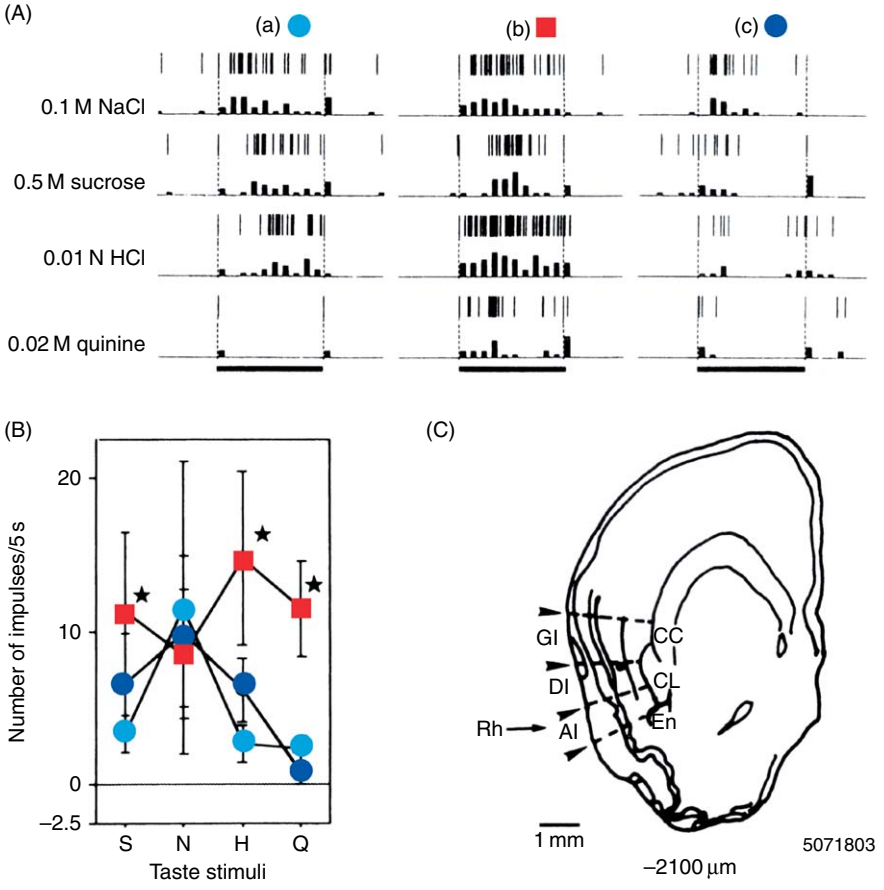

Figure 10 Example of an insular cortical neuron in which taste responses were increased in a stimulus-specific manner by the gamma-aminobutyric acid ($GABA_A$) antagonist, bicuculline. (A) Perievent histograms of a single trial (a) before, (b) during, and (c) after iontophoresis of bicuculline. (B) Mean responses for 5 s summed activity before (dark blue circles), during (red squares), and after (light blue circles). Before application of the $GABA_A$ antagonist, the neuron responded most robustly to NaCl but weakly to quinine. Following bicuculline, all of the responses, except that to NaCl, were significantly increased (asterisks), resulting in a best-stimulus change from NaCl to HCl, and an increase in breadth of tuning. (C) Location of the recorded cell in dysgranular insular (DI) cortex adapted from Ogawa, H., Hasegawa, K., Otawa, S., and Ikeda, I. 1998. GABAergic inhibition and modifications of taste responses in the cortical taste area in rats. Neurosci. Res. 32, 85–95, with permission.

stimuli were affected to varying extents, producing a net change in the chemosensitive profile, rather than a simple change in the overall level of responsiveness. Indeed the best stimulus changed in nearly half (19/43) of the cells. In contrast to other sensory cortical areas where ACh seems to sharpen tuning profiles (e.g., Sillito, A. M. and Kemp, J. A., 1983), ACh effects in taste cortex were more complex, and could give rise to either increases or decreases in neuronal selectivity. In about 2/3 of the cases, atropine antagonized the actions of ACh, suggesting a muscarinic basis; however, the remaining third of the effects were presumably nicotinic.

4.15.3.1.3.(iv) Peptides Consistent with the presence of SP and calcitonin gene-related peptide (CGRP) fibers in insular cortex, (Mantyh, P. W. and Hunt, S. P., 1984; Yasui, Y. *et al.*, 1989; Yamamoto, T. *et al.*, 1990), both peptides altered spontaneous rate, as well as taste responses in gustatory cells (Ogawa, H. *et al.*, 2000). Spontaneous rate was affected in 40% of neurons and the effects were largely (~86%) facilitory, consistent with the known cellular actions of the NK1 and CGRP receptors (Strand, F., 1999). Somewhat surprisingly, although these peptides also altered taste responses in a large proportion of insular neurons (~50%), the effects were mainly suppressive; that is, opposite to the effects on spontaneous rate, suggestive of an indirect effect through inhibitory interneurons. Furthermore, these peptides modulated responses to various taste stimuli to different degrees within individual neurons. Thus, for the three neurotransmitter systems evaluated so far, each is associated with unique net effects on spontaneous and evoked activity. However, all produce stimulus-specific alterations, which give rise to changes in response profiles in individual neurons. These diverse actions seem well suited to provide the substrate for cortical plasticity, such as those instances that have been observed during alterations of attentional state and homeostasis discussed above.

4.15.3.1.3.(v) Neurochemical substrate for conditioned taste aversion Analysis of the insular substrate important for conditioned taste aversion provides additional insights into the functions of the various neurotransmitters in taste cortex. Insular infusions of muscarinic antagonists blunt the acquisition of a conditioned taste aversion, but only if they are given prior to taste exposure, suggesting that that ACh impacts critical aspects of processing the taste signal (Ferreira, G. *et al.*, 2002). However, the effect is not simply on taste perception since infusions prior to retrieval are ineffective (Naor, C. and Dudai, Y., 1996; Berman, D. E. *et al.*, 2000). Interestingly, novel taste stimuli are much more potent in establishing an aversion, and microdialysis experiments have revealed that novel but not familiar taste stimuli elicit ACh release in the insular cortex (Miranda, M. I. *et al.*, 2000). There appears to be a complex relationship between stimulus novelty and muscarinic action in the insula, however, as muscarinic antagonists interfere only with the attenuation of neophobia, but do not abolish neophobia itself (reviewed in Bermudez-Rattoni, F. *et al.*, 2004). NMDA antagonists also blunt the acquisition of a conditioned taste aversion (Rosenblum, K. *et al.*, 1997; Gutierrez, H. *et al.*, 1999; Ferreira, G. *et al.*, 2002), but unlike muscarinic agonists, have effects when injected either before or after the presentation of the taste stimulus (Ferreira, G. *et al.*, 2002). Beta adrenergic antagonists also interfere with acquisition of a conditioned taste aversion, and unlike NMDA or muscarinic receptors, interfere with extinction once the aversion is established (Berman, D. E. and Dudai, Y., 2001). Thus multiple cortical transmitter systems have specific effects on this learned behavior. Although some of these effects may be due to short-term modulations of taste or visceral responses and second messenger systems, it is clear that long-term retention of conditioned taste aversion requires protein synthesis in insular cortex (Rosenblum, K. *et al.*, 1993). The immediate-early gene, c-fos, is a transcription factor that is differentially upregulated in the insular cortex upon exposure to novel taste stimuli (Koh, M. T. and Bernstein, I. L., 2005) and appears to serve as a critical intermediary, at least for protein synthesis required for conditioned taste aversion retention (Yasoshima, Y. *et al.*, 2006). The downstream targets of this gene are unknown, but an earlier report suggested that the amount of CGRP in insular cortex was higher after exposure to aversive compared to preferred stimuli, including a previously preferred stimulus, to which a conditioned taste aversion had been given (Yamamoto, T. *et al.*, 1990). Although this discussion focuses on the role of insular cortex in conditioned taste aversion, this does not imply that the cortex is the sole substrate for this behavior. Instead, interactions between cortical (e.g., Schafe, G. E. and Bernstein, I. L., 1998), subcortical (e.g., Schafe, G. E. and Bernstein, I. L., 1996), and brainstem sites (e.g., Reilly, S. *et al.*, 1993) are critical.

4.15.3.2 Limbic Forebrain

Structures in the limbic forebrain and hypothalamus are intimately involved in motivated behaviors, including ingestion. To maintain homeostasis, a complex neural network must integrate a wide variety of internal and external signals with past experience. Although the final consummatory sequences of eating and drinking are characterized by relatively fixed, species-specific patterns of oromotor movements, the appetitive behaviors necessary to reach this endpoint must be flexible in order to accommodate changing environmental demands. The ventral forebrain receives all the relevant information to accomplish this task, including gustatory signals.

The highly interconnected nature of forebrain circuits suggests that taste has the potential to influence a large number of limbic and hypothalamic structures. As shown in Figure 1, in the rodent, anatomical tracing experiments have demonstrated direct projections from the taste-responsive regions in the parabrachial nucleus to the central nucleus of the amygdala and the bed nucleus of the stria terminalis, as well to a contiguous ventral region including the lateral hypothalamus, substantia innominata, fundus striatum, and ventral pallidum (Norgren, R. and Leonard, C. M., 1973; Norgren, R., 1974; 1976; Bernard, J. F. *et al.*, 1993; Alden, M. *et al.*, 1994; Karimnamazi, H. and Travers, J. B., 1998). In the primate, gustatory information reaches many of these same structures, but the most direct route is likely through connections from the GC (discussed in Pritchard, T. C. and Norgren, R., 2004). In addition to this anatomical evidence, antidromic activation has been used to verify that some of the projections to the rodent lateral hypothalamus, substantia innominata, and amygdala do carry taste information (Norgren, R., 1974; 1976); this has not yet been demonstrated for the other sites. Besides this direct pathway from the PBN, there are a number of potential indirect pathways to these regions, and others. Of particular note is the projection from the insular cortex to the nucleus accumbens (Reynolds, S. M. and Zahm, D. S., 2005), a structure with a prominent role in motivational processes. However, the insular–accumbens projection does not appear to be from the primary taste cortex, that is, it is not from the dysgranular region, which receives a direct projection from the gustatory thalamus (Kosar, E. *et al.*, 1986b), nor the surrounding granular cortex, where taste responses have also been recorded (Ogawa, H. *et al.*, 1992), but rather from the ventrally adjacent agranular insular cortex (Reynolds, S. M. and Zahm, D. S., 2005). However, the dysgranular insular cortex projects to the agranular (Shi, C. J. and Cassell, M. D., 1998), providing a potential pathway for taste information to reach nucleus accumbens.

Taste responses in the limbic forebrain have been studied most frequently in the lateral hypothalamus (Burton, M. J. *et al.*, 1976; Ono, T. *et al.*, 1986; Rolls, E. T. *et al.*, 1986; Schwartzbaum, J. S., 1988) and amygdala, with an emphasis on the central nucleus (Yan, J. and Scott, T. R., 1996; Nishijo, H. *et al.*, 1998). A more recent focus has been on the nucleus accumbens (Roitman, M. F. *et al.*, 2005; Taha, S. A. and Fields, H. L., 2005) and ventral pallidum (Tindell, A. J. *et al.*, 2004; 2006). Virtually all of the recording preparations assessing gustatory responsiveness in the limbic forebrain utilize awake, behaving animals, presumably because such responses would be difficult to detect in anesthetized preparations (but see Azuma, S. *et al.*, 1984). Ample evidence for a taste influence on the limbic forebrain is provided from a score of reports of presumptive taste responses observed in the context of food or fluid rewards obtained in operant tasks. Often, these same cells are influenced by other unconditioned sensory stimuli like olfaction, or other aspects of the task, including the onset or offset of the conditioned stimulus or operant responding (e.g., Rolls, E. T. *et al.*, 1979; Sanghera, M. K. *et al.*, 1979; Schwartzbaum, J. S., 1988; Yamamoto, T. *et al.*, 1989a; Oomura, Y. *et al.*, 1991; Williams, G. V. *et al.*, 1993; Tindell, A. J. *et al.*, 2004). There is less information on the detailed nature of gustatory processing in these circuits. In the lateral hypothalamus and central nucleus of the amygdala, it is clear that taste influences just a limited proportion of encountered neurons (Schwartzbaum, J. S., 1988; Yan, J. and Scott, T. R., 1996; Nishijo, H. *et al.*, 2000), suggesting that they are a specialized population. In the nucleus accumbens and ventral pallidum, a larger proportion of neurons seems to be active during taste stimulation (Tindell, A. J. *et al.*, 2004; Roitman, M. F. *et al.*, 2005; Taha, S. A. and Fields, H. L., 2005; Tindell, A. J. *et al.*, 2006), but since different testing paradigms have been used in the various areas, direct comparisons are difficult. Compared to what is known about the thalamocortical pathway, gustatory-modulated neurons in all of the limbic-related regions appear to have a wider variety of nongustatory inputs (Oomura, Y. *et al.*, 1991; Karadi, Z. *et al.*, 1992; Nishijo, H. *et al.*, 1998), and frequently exhibit marked decrements, as well as increments in firing, in response to taste stimuli (Schwartzbaum, J. S., 1988; Oomura, Y. *et al.*, 1991; Roitman, M. F. *et al.*, 2005). Although single neurons

in the lateral hypothalamus (Yan, J. and Scott, T. R., 1996) and amygdala (Scott, T. R. *et al.*, 1993; Nishijo, H. *et al.*, 1998), respond differentially to different tastants, they do not appear to code for quality, *per se*. A systematic comparison of amygdalar and PBN taste responses in the rat instead suggested that the distinctions that amygdalar neurons make are more simply related to binary palatability decisions than those in the PBN, which make additional distinctions between different tastants (Nishijo, H. *et al.*, 1998); a detailed study in the monkey came to a similar conclusion (Scott, T. R. *et al.*, 1993). The pervasive influence of satiety on taste responses in the lateral hypothalamus and amygdala suppots a primary role for these cells in coding palatability (Burton, M. J. *et al.*, 1976; Rolls, E. T. *et al.*, 1986; Yan, J. and Scott, T. R., 1996).

Likewise, palatability appears to be a critical stimulus dimension for neurons in the nucleus accumbens and ventral pallidum. Previous studies had suggested that nucleus accumbens neurons responded to rewarding stimuli, including sweet tastes but the apparent gustatory responses had been observed during operant tasks (e.g., Nicola, S. M. *et al.*, 2004), making it unclear whether they were were innate or instead required learning and/or a more complex behavioral context. In addition, little attention had been paid to stimuli at the opposite end of the spectrum. A recent study that utilized stimulus delivery via intraoral cannulas indeed demonstrated that the hedonically negative taste stimulus, quinine, as well as hedonically positive sucrose, could drive accumbens neurons and that the responses were apparent when the animal initially encountered the gustatory stimuli; that is, learning was not required (Roitman, M. F. *et al.*, 2005). Further, different neurons responded to sucrose and quinine. Over the course of several trials, these taste cells in accumbens also developed distinctive responses to the conditioned visual and auditory stimuli that signaled tastant delivery. Similar to the unconditioned responses to the tastants themselves, neurons that responded to the sucrose cue were mostly separate from those responsive to the quinine cue although the relationships between the conditioned and unconditioned responses were complicated. This study also suggested that, for the most part, sucrose- and quinine-responsive neurons responded differentially, that is, with response decrements and increments, respectively. Another description of accumbens taste responses provides a different perspective on the significance of the excitatory and inhibitory responses (Taha, S. A. and Fields, H. L., 2005). These investigators observed accumbens activity while water-deprived rats licked water and varying concentrations of sucrose. Similar to what Roitman and coworkers observed, most responses to sucrose were inhibitory. However, these inhibitory responses appeared most directly related to the licking behavior, *per se*. Decrements did not vary as a function of sucrose concentration, and licking to water or even a dry spout resulted in similar decreases in firing rate. However, in agreement with the other report, these investigators also observed a small population of sucrose-driven responses, which exhibited positive concentration–response functions. Furthermore, the excitatory responses were modulated by context, since a given concentration of sucrose elicited larger responses when paired with water, than with a higher concentration of sugar. Such a contrast paradigm is well-known to change the reward value of a gustatory stimulus (Flaherty, C. F. *et al.*, 1994).

The ventral pallidum, a target of accumbens projections (reviewed in Zahm, D. S., 2000) also contains gustatory-responsive neurons whose firing rates are modulated by the hedonic nature of the stimulus (Tindell, A. J. *et al.*, 2004; 2006). An experiment which tracked pallidal taste responses before, during, and after induction of a salt appetite is particularly illuminating in this regard (Tindell, A. J. *et al.*, 2006) (Figure 11).

Prior to and following sodium deprivation, ventral pallidal neurons responded more robustly to a highly preferred concentration of sucrose (0.5 M) than to a highly aversive, hypertonic (1.5 M) concentration of sodium chloride. Following deprivation, this same concentration of salt elicited parallel increases in positively hedonic behaviors and firing in ventral pallidal neurons. In fact, firing rates to sodium were now equivalent to those elicited by sucrose. Interestingly, deprivation also caused pallidal neurons to become more broadly tuned, at least with regard to the limited number of taste qualities tested. When neurons were classified as a function of responsiveness to sucrose, salt, and water, the largest proportion of neurons responded to one of the stimuli prior to deprivation, in contrast to all three during the deprived state. These results provide a rather dramatic example of gustatory malleability in the face of changing homeostatic demands.

4.15.4 Conclusions

The critical role of the gustatory system in guiding feeding behavior is accomplished by a network characterized by a high degree of discriminative and

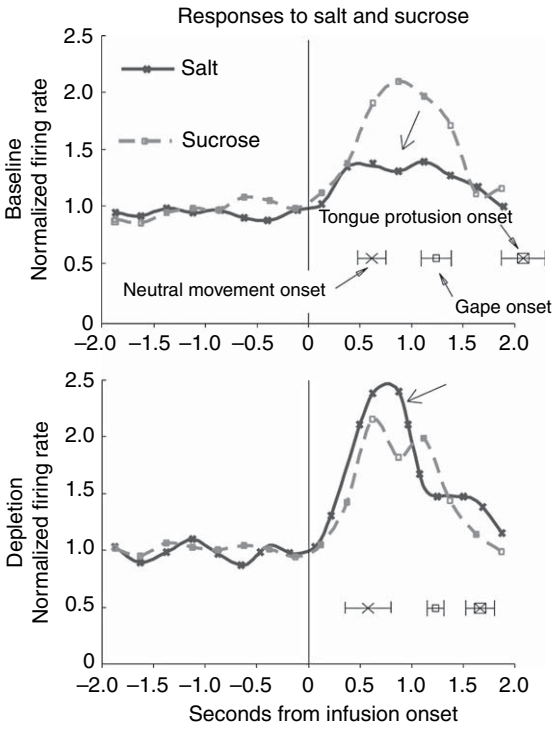

Figure 11 Mean firing rate of ventral pallidum neurons during infusions of 0.5 M sucrose (dotted line) and 1.5 M NaCl (solid line) during a normal homeostatic state (top graph) and during sodium deprivation (bottom graph). In the normal state, palatable sucrose induces a brief, twofold increase in firing rate but NaCl elicits a much smaller response. Under the sodium deprivation condition, when NaCl is as palatable as sucrose, both stimuli elicit similar increases in the activity of ventral pallidal neurons. The symbols beneath the neural responses indicate the onset of the oromotor responses elicited by these stimuli. The onset of the neural response precedes licking or gaping, but is not tightly coupled to these behaviors. From Tindell, A. J., Smith, K. S., Pecina, S., Berridge, K. C. and Aldridge, J. W. 2006. Ventral pallidum firing codes hedonic reward: when a bad taste turns good. J. Neurophysiol. 96, 2399–2409, with permission.

integrative capacity, and an equally high degree of plasticity necessary to meet shifting environmental and homeostatic demands. The operations of this system have become increasingly clarified, but key questions remain unanswered. First, the central code(s) for taste quality remains an area of active investigation (see Chapters Neural Ensembles in Taste Coding and A Perspective on Chemosensory Quality Coding). The broad tuning of many central neurons is suggestive of an ensemble code, but its precise nature, including the size and dynamic aspects of the necessary ensemble, are just now coming to light. In addition, there is a subset of more narrowly tuned central neurons. It is unclear whether such cells simply comprise part of an ensemble code, or instead are a specialized subpopulation that uses a sparse code to accomplish particular functions. It has become increasingly apparent that single central taste neurons also can respond to olfactory and somatosensory stimuli. The likely function of such convergence is to give rise to the compound sensation of flavor. Human imaging studies further suggest that integration between modalities not only requires special combinations of stimuli, but also relies upon learning. However, the way in which single gustatory neurons combine these multiple aspects of a compound flavor stimulus signals requires much more scrutiny. Similarly, the list of manipulations that can modify taste responses, including changes in homeostatic state, learning, modulation by neurotransmitters, and activiation of other neural structures, is continuing to grow. The challenge is to be able to define how these changes relate mechanistically to one another, and which changes in neural responsiveness comprise the critical alternations that drive adaptive behavior.
